The three components of ϱ along the principal axes and the magnitude of the vector are given by Eq. (2-30). By expressing Eq. (2-3) in terms of ω, ω_1, and α, one obtains

$$T=\tfrac{1}{2}(\omega-\omega_1)^+\cdot\mathbf{I}\cdot(\omega-\omega_1)$$
$$-\tfrac{1}{2}\omega_1^+\cdot\mathbf{I}\cdot\omega_1+\tfrac{1}{2}(\partial\alpha/\partial t)^+\cdot\mathbf{I}_\alpha\cdot(\partial\alpha/\partial t). \tag{2-34}$$

The substitution of Eq. (2-32b) into Eq. (2-34) yields

$$T=\tfrac{1}{2}(\omega+\varrho\dot{\alpha})^+\cdot\mathbf{I}\cdot(\omega+\varrho\dot{\alpha})+\tfrac{1}{2}(\mathbf{I}_\alpha-\varrho^+\cdot\mathbf{I}\cdot\varrho)\dot{\alpha}^2$$
$$=\tfrac{1}{2}\textstyle\sum_{jk}I_{jk}(\omega_j+\rho_j\dot{\alpha})(\omega_k+\rho_k\dot{\alpha})+\tfrac{1}{2}rI_\alpha\dot{\alpha}^2.$$

The resulting Hamiltonian is

$$H=\frac{\hbar^2}{2}\sum_{jk}I_{jk}^{-1}P_jP_k+\frac{\hbar^2}{2}\left(\frac{1}{rI_\alpha}\right)(p-\Pi)^2+V(\alpha), \tag{2-35}$$

where

$$\Pi=\rho_bP_b+\rho_cP_c=\varrho\cdot\mathbf{P}.$$

This Hamiltonian is the same as Eq. (2-25). A rotation of the c axis to the ϱ direction (c' direction) brings the Hamiltonian to the form given in Eq. (2-29) which then can be transformed to Eq. (2-31). This transformation is not strictly necessary since the quantum-mechanical matrix elements can be determined from Eq. (2-29) as well as Eq. (2-31) with only a different torisonal wave function. This point is discussed in Sec. 3.

Finally, two other types of molecular symmetry have been considered in the literature. Molecules with two perpendicular planes of symmetry, e.g., nitromethane, have been considered by Wilson *et al.*[121] and by Tannenbaum, Johnson, Meyers, and Gwinn.[106,107] Here all the previous formulas apply with $I_{bc}=0$. Molecules with no planes of symmetry have been treated by Hecht and Dennison[20] and by Burkhard,[7] and the method is similar to that outlined in this section.

B. Principal Axes Method (PAM)[11a,23,101,119,121]

In the PAM the symmetric top Hamiltonian is given by Eq. (2-6) with the principal axes x, y, and z coincident with the a, b, and c axes. The transformation (2-8) is not applied. In this method (for an asymmetric molecule) a coordinate system x, y, and z, rigidly attached to the framework of the molecule, is used. Furthermore, this set of axes is chosen to be the principal axes of the entire molecule with the origin at the center of mass so that the principal moments of inertia I_x, I_y, and I_z†† of the molecule are used. The orientation of the principal axes relative to the framework is not altered by the rotation of the top because of its cylindrical symmetry. Therefore from Eq. (2-3), the kinetic energy for an asymmetric molecule has the form

$$T=\tfrac{1}{2}I_x\omega_x^2+\tfrac{1}{2}I_y\omega_y^2+\tfrac{1}{2}I_z\omega_z^2+I_\alpha\lambda_x\omega_x\dot{\alpha}$$
$$+I_\alpha\lambda_y\omega_y\dot{\alpha}+I_\alpha\lambda_z\omega_z\dot{\alpha}+\tfrac{1}{2}I_\alpha\dot{\alpha}^2, \tag{2-36}$$

where ω_x, ω_y, and ω_z are the components of the angular velocity along the principal axes, and λ_x, λ_y, and λ_z are the direction cosines of the symmetry axis of the top to the principal axes. In terms of the momenta defined as

$$P_i=\partial T/\partial\omega_i\quad(i=x,y,z),$$
$$p=\partial T/\partial\dot{\alpha},$$

the Hamiltonian can be written in the form[101]

$$H=A_xP_x^2+B_yP_y^2+C_zP_z^2+\tfrac{1}{2}\sum_{x,y,z,i\neq j}D_{ij}(P_iP_j+P_jP_i)$$
$$-2\sum_{x,y,z}Q_iP_ip+Fp^2+V(\alpha), \tag{2-37}$$

where

$$A_x=\frac{\hbar^2}{2I_x}\left[1+\frac{\lambda_x^2I_\alpha}{rI_x}\right]=\frac{\hbar^2}{2I_x}+F\rho_x^2,$$

and similarly for B_y and C_z by the permutation (x, y, z),

$$D_{ij}=\frac{\hbar^2}{2}\frac{\lambda_i\lambda_jI_\alpha}{rI_iI_j}=F\rho_i\rho_j\quad(i,j=x,y,z\text{ and }i\neq j),$$

$$Q_i=\frac{\hbar^2\lambda_i}{2rI_i}=F\rho_i\quad(i=x,y,z),$$

$$F=\hbar^2/2rI_\alpha,$$

$$\rho=(\rho_x^2+\rho_y^2+\rho_z^2)^{\frac{1}{2}}=\left[\sum_{g=x,y,z}\left(\frac{\lambda_gI_\alpha}{I_g}\right)^2\right]^{\frac{1}{2}},\quad \rho_g=\lambda_gI_\alpha/I_g,$$

$$r=1-\frac{\lambda_y^2I_\alpha}{I_y}-\frac{\lambda_z^2I_\alpha}{I_z}.$$

†† Note that the notation I_x, I_y, and I_z is used instead of I_{xx}, I_{yy}, and I_{zz} because of the absence of the product of inertia terms.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Alternatively one may express the Hamiltonian[25a] as

$$H=(\hbar^2/2rI_\alpha)(p-\Pi)^2+(\hbar^2/2)\sum_g P_g^2/I_g+V(\alpha), \quad (2\text{-}38)$$

where

$$\Pi=\varrho\cdot\mathbf{P}=\sum_g\rho_g P_g=(\lambda_x I_\alpha/I_x)P_x +(\lambda_y I_\alpha/I_y)P_y+(\lambda_z I_\alpha/I_z)P_z.$$

The similarity between Eqs. (2-38) and (2-35) should be noted.

From Eq. (A1-7) it is clear that P_x, P_y, and P_z represent the three components of the total angular momentum defined in the usual way. The commutation relations between the various momenta can be summarized as

$$(P_i,P_j)=-i\hbar P_k \quad (i,j,k=x,y,z \text{ in cyclic order}),$$
$$(p,P_i)=0.$$

Furthermore, the coupling between over-all rotation and internal rotation is apparent in the Hamiltonian by the cross terms pP_i, etc.

For the molecules with a plane of symmetry in their framework all the above formulation applies with $\lambda_x=0$ (or $\lambda_y=0$).[68,38] With two planes of symmetry both of the direction cosines are set to zero.[121]

C. Comparison of the Two Methods

The chief difference between the two methods lies in the different choice of coordinate axes. Hence, the Hamiltonian functions can be transformed to each other simply through a coordinate transformation which is given in the first part of this section. In the second part the Schroedinger equations in terms of the Eulerian angles are given for each method. While it is not necessary to express the Hamiltonian and the wave function in the coordinate representation in order to find the energy levels, a comparison of the momentum operators in terms of the Eulerian angles does show more clearly the difference between the two formulations.

1. Connecting relations.—For the purpose of demonstrating the connection between the two procedures a molecule with a plane of symmetry is taken. The relation between the components of a vector $\mathbf{r}$ in the principal axes x, y, z and the set of axes a, b, c, defined in the internal axis method is

$$\begin{bmatrix} r_a \\ r_b \\ r_c \end{bmatrix}=\begin{bmatrix} 1 & 0 & 0 \\ 0 & \lambda_z & -\lambda_y \\ 0 & \lambda_y & \lambda_z \end{bmatrix}\begin{bmatrix} r_x \\ r_y \\ r_z \end{bmatrix}. \quad (2\text{-}39)$$

The various terms in these two systems are then related by the equations

$$I_{bb}=\lambda_z^2 I_y+\lambda_y^2 I_z,$$
$$I_{cc}=\lambda_z^2 I_z+\lambda_y^2 I_y,$$
$$I_{bc}=\lambda_y\lambda_z(I_z-I_y),$$
$$I_{aa}=I_x,$$

$$r=\frac{I_{bb}I_{cc}-I_{bb}I_a-I_{bc}^2}{I_{bb}I_{cc}-I_{bc}^2}=1-\frac{\lambda_y^2 I_\alpha}{I_y}-\frac{\lambda_z^2 I_\alpha}{I_z}, \quad (2\text{-}40)$$

$$\rho=\frac{(I_{bb}^2+I_{bc}^2)^{\frac{1}{2}}I_\alpha}{(I_{bb}I_{cc}-I_{bc}^2)}=\left(\frac{\lambda_y^2 I_\alpha^2}{I_y^2}+\frac{\lambda_z^2 I_\alpha^2}{I_z^2}\right)^{\frac{1}{2}}.$$

From these formulas one can prove the equivalence of Eq. (2-25) or Eq. (2-35) and Eq. (2-37) or Eq. (2-38).

2. Comparison by Eulerian angles.—(*a*) *Principal axes method:* To express the angular momentum operators in coordinate representation use is made of the relation

$$P_x=\frac{\partial T}{\partial\omega_x}=\frac{\partial\dot\theta}{\partial\omega_x}\frac{\partial T}{\partial\dot\theta}+\frac{\partial\dot\Phi}{\partial\omega_x}\frac{\partial T}{\partial\dot\Phi}+\frac{\partial\dot\chi}{\partial\omega_x}\frac{\partial T}{\partial\dot\chi}$$
$$=\frac{\partial\dot\theta}{\partial\omega_x}P_\theta+\frac{\partial\dot\Phi}{\partial\omega_x}P_\Phi+\frac{\partial\dot\chi}{\partial\omega_x}P_\chi. \quad (2\text{-}41)$$

Since ω_x, ω_y, and ω_z constitute the angular velocity of the framework of the molecule, they are related to the Eulerian angles describing the orientation of the framework through the equations

$$\omega_x=\dot\theta\sin\chi-\dot\Phi\sin\theta\cos\chi,$$
$$\omega_y=\dot\theta\cos\chi+\dot\Phi\sin\theta\sin\chi, \quad (2\text{-}42)$$
$$\omega_z=\dot\chi+\dot\Phi\cos\theta.$$

The quantum-mechanical operators for P_x, P_y, and P_z are readily obtained if one replaces p_θ by $(\hbar/i)(\partial/\partial\theta)_{\Phi\chi\alpha}$, etc. It follows that

$$\frac{iP_x}{h}=\sin\chi\left(\frac{\partial}{\partial\theta}\right)_{\Phi\chi\alpha}-\cos\chi\csc\theta\left(\frac{\partial}{\partial\Phi}\right)_{\theta\chi\alpha} +\cos\chi\cot\theta\left(\frac{\partial}{\partial\chi}\right)_{\theta\Phi\alpha}$$
$$\frac{iP_y}{h}=\cos\chi\left(\frac{\partial}{\partial\theta}\right)_{\Phi\chi\alpha}+\sin\chi\csc\theta\left(\frac{\partial}{\partial\Phi}\right)_{\theta\chi\alpha} -\sin\chi\cot\theta\left(\frac{\partial}{\partial\chi}\right)_{\theta\Phi\alpha}$$
$$\frac{iP_z}{h}=\left(\frac{\partial}{\partial\chi}\right)_{\theta\Phi\alpha}. \quad (2\text{-}43)$$

These expressions for the angular momentum are identical to those for a rigid rotor, and the customary commutation rules can thereby be established. Since $\omega_x, \omega_y, \omega_z$ have no dependence on $\dot\alpha$ and α, one can see that

$$p=(\partial T/\partial\dot\alpha)_{\omega_x,\omega_y,\omega_z}=(\partial T/\partial\dot\alpha)_{\theta\Phi\chi}, \quad (2\text{-}44)$$

and the quantum-mechanical for p is, accordingly,

$$p=\frac{h}{i}\left(\frac{\partial}{\partial\alpha}\right)_{\theta\Phi\chi}. \quad (2\text{-}45)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Inspection of Eqs. (2-43) and (2-45) confirms the commutation relation

$$pP_i - P_i p = 0, \quad i = x, y, z.$$

Equations (2-43) and (2-45) may now be substituted in the Hamiltonian in order to derive the desired wave equation.

(*b*) *Internal axis method:* The coordinate transformation from θ, Φ, χ, α to θ, Φ, χ', α', as described in Eq. (2-15), can be used to express P_a, P_b, P_c', and p' in terms of the new set of variables

$$\begin{aligned}(\partial/\partial\chi)_\alpha &= (\partial/\partial\chi')_{\alpha'} \\ (\partial/\partial\alpha)_\chi &= \rho(\partial/\partial\chi')_{\alpha'} + (\partial/\partial\alpha')_{\chi'}.\end{aligned} \tag{2-46}$$

Equation (2-46) is valid so long as the c axis is parallel to the bond connecting the framework and the top. However, after the transformation Eq. (2-27), this is no longer true and the Eulerian angles χ, α, χ', and α' are related by more complicated expressions [see Eq. (8) of reference (20)]. In order to simplify the mathematical details, only Eq. (2-46) is used.

It is now possible to write with the aid of Eqs. (2-15) and (2-46),‡‡ the following angular momenta,

$$\begin{aligned}P_a &= \cos\rho\alpha' P_a^{\chi'\alpha'} - \sin\rho\alpha' P_b^{\chi'\alpha'}, \\ P_b &= \sin\rho\alpha' P_a^{\chi'\alpha'} + \cos\rho\alpha' P_b^{\chi'\alpha'}, \\ P_c &= \frac{h}{i}\left(\frac{\partial}{\partial\chi'}\right)_{\theta\Phi\alpha'},\end{aligned} \tag{2-47}$$

where

$$P_a^{\chi'\alpha'} = \frac{h}{i}\left[\sin\chi'\left(\frac{\partial}{\partial\theta}\right)_{\Phi\chi'\alpha'} - \cos\chi'\csc\theta\left(\frac{\partial}{\partial\Phi}\right)_{\theta\chi'\alpha'} + \cos\chi'\cot\theta\left(\frac{\partial}{\partial\chi'}\right)_{\theta\Phi\alpha'}\right], \tag{2-48}$$

$$P_b^{\chi'\alpha'} = \frac{h}{i}\left[\cos\chi'\left(\frac{\partial}{\partial\theta}\right)_{\Phi\chi'\alpha'} + \sin\chi'\csc\theta\left(\frac{\partial}{\partial\Phi}\right)_{\theta\chi'\alpha'} - \sin\chi'\cot\theta\left(\frac{\partial}{\partial\chi'}\right)_{\theta\Phi\alpha}\right].$$

The two superscripts on P_a and P_b denote two of the four "independent variables" (the other two being always θ and Φ) one chooses in taking the partial derivatives. One might well recognize that $P_a^{\chi'\alpha'}$ and $P_b^{\chi'\alpha'}$ have almost the same form as P_x and P_y in Eq. (2-43) (which in our present notation, would be written as $P_x^{\chi\alpha}$ and $P_y^{\chi\alpha}$) aside from the fact that χ' and α' are used as variables for one case while χ and α are used for the other. It is important to specify the independent variables in the partial derivatives because Eq. (2-46) shows that $(\partial/\partial\alpha)_\chi$ is different from $(\partial/\partial\alpha)_{\chi'}$ and also from $(\partial/\partial\alpha')_{\chi'}$. Since P_a and P_b involve all four angular variables, the eigenfunctions of the operator

$$P_a^2/2I_a + P_b^2/2I_b + P_{c'}^2/2I_c$$

depend on the internal coordinate α', in addition to the three Eulerian angles, in a rather complex manner. For example, these functions are not identical to the asymmetric top wave function. It is apparent that the absence of the cross product between the two kinds of momentum operators in Eq. (2-29) does not signify a complete separation between the external and internal coordinates inasmuch as the P's are actually functions of α. When the momentum operators in Eq. (2-26) are written in their differential form given in Eqs. (2-47) and (2-48) [where ρ is I_a/I_{cc} from Eq. (2-8)], the Schroedinger equation is obtained. This equation was given by Burkhard and Dennison.§§

The rather unsatisfactory feature of having α' mixed in the P's can be removed by a transformation which is the inverse of Eq. (2-47), i.e., introducing P_a' and P_b' so that

$$\begin{pmatrix} P_a' \\ P_{b'} \end{pmatrix} = \begin{pmatrix} \cos\rho\alpha & \sin\rho\alpha \\ -\sin\rho\alpha & \cos\rho\alpha \end{pmatrix}\begin{pmatrix} P_a \\ P_b \end{pmatrix} = \begin{pmatrix} P_a^{\chi'\alpha'} \\ P_b^{\chi'\alpha'} \end{pmatrix}. \tag{2-49}$$

This transformation is similar to the one employed previously in Eq. (2-17) in connection with the internal rotation axes. Equation (2-49) shows that P_a' and P_b' do not contain α explicitly and thus commute with p'.

The Hamiltonian may then be written in the Schroedinger representation with the aid of Eqs. (2-48) and (2-49).

3. HIGH BARRIER APPROXIMATIONS

In Sec. 2 the Hamiltonians were derived for various coordinate systems and for molecules of various kinds of symmetry. These Hamiltonians can generally be divided into three parts: the over-all rotational part, the internal rotation torsional part, and a coupling between over-all rotation and internal rotation. Since the separation is not complete, except in the case of a symmetric type molecule, the Schroedinger equation cannot be solved exactly; perturbation theory is usually applied. For ease in computation we use a matrix formulation, and two approximate methods for diagonalizing the matrix are commonly used. The high barrier approximation is applicable to the cases where the separations of the torsional energy levels are large compared with the rotational energy separations. The other is the low barrier approximation where the problem of the free internal rotor is first solved and the barrier treated as a perturbation. Section 4 deals with this low barrier approximation.

‡‡ These may be obtained by a procedure similar to that employed in Eq. (2-41), i.e., from the relations

$$P_a = \frac{\partial\theta}{\partial\omega_a}P_\theta + \frac{\partial\Phi}{\partial\omega_a}P_\Phi + \frac{\partial\chi'}{\partial\omega_a}P_{\chi'} + \frac{\partial\alpha'}{\partial\omega_a}p, \text{ etc.}$$

§§ See p. 411 of reference 8.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The Schroedinger equation for a high barrier can be solved by using either the PAM or IAM.

In the PAM the energy matrix is constructed in a representation in which the over-all rotation part and the internal torsion part of the Hamiltonian are separately diagonal. The cross terms (coupling terms) between the total angular momentum and the internal angular momentum are chosen as the perturbation. The basis functions are then the product of the rigid symmetric rotor wave functions and the functions of the internal angle α, known as the torsional functions which are related to the tabulated Mathieu functions. The perturbation terms are treated by the Van Vleck transformation[34] so that after this transformation the secular equation can be approximately factored into blocks corresponding to the different torsional states. Associated with each torsional state there are two different submatrices in the energy matrix and thus two sets of rotational levels. From the separation of the pair of spectral lines arising from a given rotational transition in the two sets of rotational levels, the barrier hindering internal rotation is determined.

In the IAM the Nielsen transformation (or the modified form given by Hecht and Dennison[20] or Itoh[31]) is applied to the Hamiltonian so that the coupling terms between the internal and external coordinates in the transformed Hamiltonian are completely removed or become much smaller than those which occur in the PAM, and hence can be treated by perturbation method more readily. The basis functions of the energy matrix are again taken as the product of the rigid symmetric rotor functions and the torsional functions which are the solution of a differential equation similar to the Mathieu equation. The torsional functions here are different from those in PAM because of the different boundary conditions as explained in Sec. I. B. Because of the interaction of the external and internal rotation, the torsional functions depend on the quantum number K and, in principle, the differential equation for the torsional functions should be solved for each value of K. Since it is necessary to have the torsional functions in order to evaluate the elements of the energy matrix, the determination of the torsional functions becomes one of the major difficulties of this method. Approximate formulas[20] have been derived for the matrix elements involving the torsional functions. At the high barrier approximation the infinite energy matrix can be reduced to a series of $(2J+1)\times(2J+1)$ blocks, corresponding to the case of limiting rigid rotor. Since the coordinate axes used in setting up the Hamiltonian in Eq. (2-25) are not the principal axes for the asymmetric rotor, a coordinate transformation to the principal axes should be made so as to simplify the solution of the secular equation. When this is done, each of the submatrices becomes very similar to that of a rigid rotor with some additional elements which represent the effect of the internal torsion on the over-all rotation. From the structure of the energy levels it was found that each of the rigid-rotor spectral lines is split into a doublet as also predicted by the PAM. The relations between the separations of the doublets to the barrier height have been given by Hecht and Dennison[20] and also by Lide and Mann.[62] These approximate equations are equivalent to those derived by PAM so that one has in many cases an equal choice as to which method to use: PAM or IAM. In the discussion to follow the symmetric molecule is covered first by the PAM and the IAM. With these principles in mind the effect of asymmetry in the molecular frame is introduced into both the PAM and the IAM.

I. Symmetric Molecules

A. Principal Axes Method (PAM)

As derived in the previous section [see Eq. (2-6)], the Hamiltonian for this class of molecules can be written as

$$H=H_R+H_T+H_{IR}, \tag{3-1}$$

where

$$H_R=A_x(P_x^2+P_y^2)+C_zP_z^2,$$

$$H_T=Fp^2+V(\alpha),$$

$$H_{IR}=-2C_zP_zp,$$

$$A_x=\frac{h^2}{2I_x}=\frac{h^2}{2I_y}, \tag{3-2}$$

$$C_z=\frac{h^2}{2(I_z-I_\alpha)}=\frac{h^2}{2I_z}+F\rho^2,$$

$$F=\frac{h^2}{2rI_\alpha}=\frac{h^2I_z}{2I_\alpha(I_z-I_\alpha)}.$$

Here, H_R and H_T comprise, respectively, the terms describing the over-all rotation and internal rotation, and H_{IR} represents the interaction term.‖‖ In the calculation of the energy levels of H, we take H_R+H_T as the unperturbed Hamiltonian and treat H_{IR} as the perturbation. Since H_{IR} does not vanish at the limit of infinite barrier, the effect of the perturbation is not *small*. Consequently, for molecules with an intermediate barrier, fourth-order perturbation procedure must be applied in order to obtain accurate results for the barrier heights. Nevertheless, the advantages of this approach will be seen.

1. Rotational equation H_R.—The eigenfunctions of H_R are the symmetric rotor functions and they are usually expressed as

$$S_{JKM}(\theta,\varphi)e^{iK\chi},$$

where J is the total angular momentum and K and M are the projection of J on the body-fixed and space-fixed axes, respectively. The energy and the matrix

‖‖ For a discussion of the "interaction" between over-all and internal rotation see the last paragraph of Sec. 2 II. A1.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

elements of P are

$$E=A_x J(J+1)+(C_z-A_x)K^2,$$
$$(JK|P^2|JK)=J(J+1)\hbar^2,$$
$$(JK|P_z|JK)=K\hbar.$$

The rotational constant, C_z, associated with P_z^2 is not that of the limiting rigid rotor and hence H_R does not represent the entire Hamiltonian for the case of infinite barrier height. The reduction of H into the rigid-rotor Hamiltonian for the limiting high barrier is discussed in Sec. I. A5.

2. Torsional equation H_T.—(a) Eigenfunctions and eigenvalues: The eigenfunction $U(\alpha)$ and the eigenvalues E of H_T are to be determined from the differential equation

$$[-Fd^2/d\alpha^2+V(\alpha)]U(\alpha)=EU(\alpha). \tag{3-3}$$

Physically we know that $U(\alpha)$ must be periodic in 2π. When $V(\alpha)$ is taken as a simple sinusoidal function such as $\frac{1}{2}V_3(1-\cos 3\alpha)$, the above equation can readily be transformed through the substitutions

$$\begin{aligned} 3\alpha+\pi&=2x, & s&=4V_3/9F,\\ U[(3\alpha+\pi)/2]&=M(x), & b&=4E/9F, \end{aligned} \tag{3-4}$$

to the Mathieu equation

$$d^2M(x)/dx^2+[(b-\tfrac{1}{2}s)-\tfrac{1}{2}s\cos 2x]M(x)=0. \tag{3-5}$$

The solutions of Eq. (3-5) may be expanded by Fourier series

$$M(x)=\sum_k c_k \cos kx+d_k \sin kx.$$

Since Eq. (3-5) is invariant under the operation $x\rightarrow -x$, $x\rightarrow x+\pi$, the eigenfunctions of Eq. (3-5) have one of the following forms[104]:

$$Se_{2r}(s,x)=\sum_k De_{2k}^{(2r)} \cos 2kx \qquad \text{(period } \pi\text{)} \tag{3-6a}$$

$$Se_{2r+1}(s,x)=\sum_k De_{2k+1}^{(2r+1)} \cos(2k+1)x \qquad \text{(period } 2\pi\text{)} \tag{3-6b}$$

$$So_{2r}(s,x)=\sum_k Do_{2k}^{(2r)} \sin 2kx \qquad \text{(period } \pi\text{)} \tag{3-6c}$$

$$So_{2r+1}(s,x)=\sum_k Do_{2k+1}^{(2r+1)} \sin(2k+1)x \qquad \text{(period } 2\pi\text{)}. \tag{3-6d}$$

Here s is a parameter associated with the differential equation (3-5). For each type of the functions, $Se(s,x)$ and $So(s,x)$, one finds a series of eigenfunctions and they are labeled by the superscript r. The values of b corresponding to these functions are denoted by be_{2r}, be_{2r+1}, bo_{2r}, bo_{2r+1}. When Eqs. (3-6) are substituted in Eq. (3-5), four different infinite secular equations are obtained from which the eigenvalues can be determined. This procedure can be carried out in a systematic fashion which is described in Appendix 2. The Fourier coefficients of the eigenfunctions are then obtained from the recursion relations associated with the infinite determinantal equations. The eigenvalues and the Fourier coefficients of the associated eigenfunctions can be found in the *Tables Relating to Mathieu Functions*.[104]

From the torsional equation one may readily see that since the C_3 group operations leave Eq. (3-3) invariant¶¶; the solution of this equation can be expanded in the form

$$\sum_k A_{3k} e^{i3k\alpha} \qquad (A) \tag{3-7a}$$

$$\sum_k A_{3k+1} e^{i(3k+1)\alpha} \qquad (E_1) \tag{3-7b}$$

$$\sum_k A_{3k-1} e^{i(3k-1)\alpha} \qquad (E_2) \tag{3-7c}$$

corresponding to the symmetry species A and E of the C_3 group. The first form of the expansion in Eq. (3-7) gives rise to nondegenerate eigenfunctions while the last two constitute the doubly degenerate pairs. The series of eigenvalues and eigenfunctions of the nondegenerate solutions can be obtained from the tabulated Mathieu functions with period π, Eqs. (3-6a) and (3-6c), after the slight modification as set down in Eq. (3-4). The degenerate solutions have been tabulated recently by Kilb.[36] The relations between the notations adopted here and those used in the various tabulations may be summarized as follows:

$E_{v\sigma}=9Fb_{v\sigma}/4$, $s=4V_3/9F$, $2x=3\alpha+\pi$

	A levels ($\sigma=0$)		E levels ($\sigma=\pm 1$)	
v	$b_{v\sigma}$	reference 104	$b_{v\sigma}$	reference 36
0	b_{00}	be_0	$b_{01}(b_{0-1})$	b_0
1	b_{10}	bo_2	$b_{11}(b_{1-1})$	b_{-1}
2	b_{20}	be_2	$b_{21}(b_{2-1})$	b_1
3	b_{30}	bo_4	$b_{31}(b_{3-1})$	b_{-2}
4	b_{40}	be_4	$b_{41}(b_{4-1})$	b_2
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.

(3-8)

Each member of the series of the degenerate and nondegenerate solutions is labeled by the index v with $v=0$ for the lowest eigenvalue. At very high barriers the spacings between the nondegenerate and degenerate energy levels of the torsional equation associated with a given v are much smaller than those between levels with different v (see Fig. 1). For this reason, the index v is called the torsional quantum number and the different energy levels associated with a given v are thought of as the torsional sublevels belonging to the same torsional state. The sublevels are distinguished by the index σ with $\sigma=0$ for the nondegenerate level (species A) and $\sigma=\pm 1$ for the levels of species E (E_1: $\sigma=+1$, E_2: $\sigma=-1$). In Fig. 2 the energy levels are plotted as a function of the barrier height from free internal rotation to a relatively high barrier. The solution of the free rotational energy levels and the meaning of the "m" quantum number are discussed in Sec. 4.

A solution of the torsional equation can then be written as

$$U_{v\sigma}(\alpha)=\sum_k A_{3k+\sigma^v} e^{i(3k+\sigma)\alpha}, \tag{3-9}$$

¶¶ Strictly speaking, Eq. (3-3) belongs to the C_{3v} group. However, in the present discussion, it is more convenient to consider only the subgroup C_3.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and the eigenvalues associated with these functions are correspondingly denoted by $E_{v\sigma}$.

(*b*) *Harmonic oscillator approximation:* With a very high barrier the internal motion degenerates into small oscillations, and the potential energy $\frac{1}{2}V_3(1-\cos 3\alpha)$ may be expanded about the equilibrium point yielding $(9/4)V_3\alpha^2$. The torsional wave function in the vicinity of the equilibrium configuration can be approximated by the harmonic oscillator functions which are denoted as $H_v(\alpha)$. The corresponding eigenvalues are

$$E_v=3(V_3F)^{\frac{1}{2}}(v+\tfrac{1}{2}). \tag{3-10}$$

There are three functions of $H_v(\alpha)$; one situated at each of three potential minima. These functions are denoted by $H_v^{(1)}$, $H_v^{(2)}$, and $H_v^{(3)}$. When the tunneling effect is considered, the correct zeroth-order torsional functions are[20,99]

$$U_{v,0}(\alpha)=\frac{1}{\sqrt{3}}[H_v^{(1)}+H_v^{(2)}+H_v^{(3)}],$$

$$U_{v,1}(\alpha)=\frac{1}{\sqrt{3}}[H_v^{(1)}+\omega H_v^{(2)}+\omega^2 H_v^{(3)}], \tag{3-11}$$

$$U_{v,-1}(\alpha)=\frac{1}{\sqrt{3}}[H_v^{(1)}+\omega^2 H_v^{(2)}+\omega H_v^{(3)}],$$

where $\omega=\exp(2\pi i/3)$ and v, as before, denotes the torsional quantum number. The first function in Eq. (3-11) is nondegenerate (A levels) and the last two are degenerate (E levels).

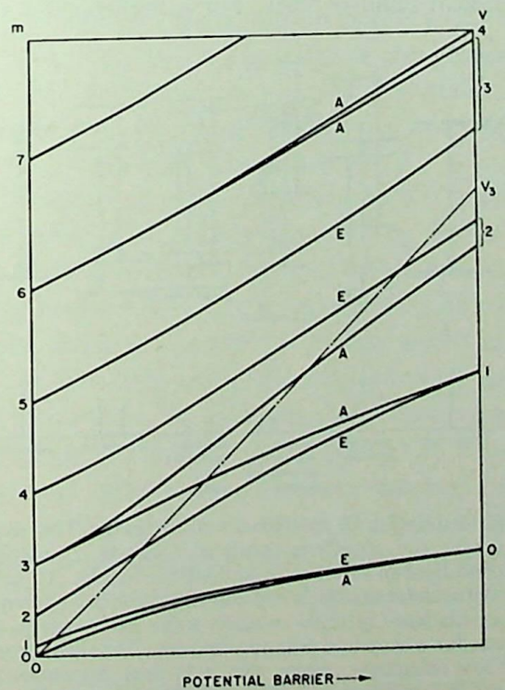

FIG. 2. The hindered internal rotational energy levels as a function of the barrier height. The free rotation quantum numbers m are at the left ordinate, i.e., a zero barrier, and the torsional quantum numbers v are on the right ordinate, i.e., a relatively high barrier. The diagonal line V_3 shows the actual height of the barrier in relation to the energy levels. Those energy levels below the top of the barrier are clearly discernible.

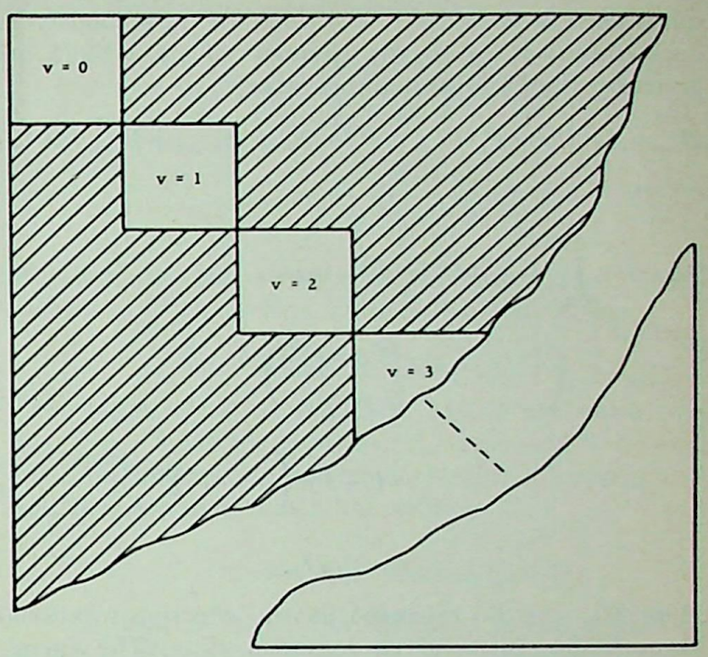

FIG. 3. The torsional matrix. Each block on the diagonal contains the over-all rotation and internal rotational matrix elements associated with that torsional level. The shaded area represents the coupling between the rotational levels of the various torsional states. With the Van Vleck transformation the matrix elements in these shaded areas are folded into the blocks on the diagonal.

3. *Perturbation treatment.*—The energy matrix for H as given in Eqs. (3-1) and (3-2) is now constructed in a representation in which H_R and H_T are diagonal. From Eq. (3-9) it is obvious that p is diagonal in the quantum number σ but not in v. Consequently, the secular equation can be grouped into blocks corresponding to different v and σ. Within each block the Hamiltonian is given by H_R+H_T, and blocks of different v are connected by the matrix elements of H_{IR}. If the energy separations between different torsional states are large compared to those between rotational levels of the same v, a VanVleck transformation[34] may be applied to the energy matrix to reduce the matrix elements nondiagonal in v to the second order; such matrix elements can then contribute only fourth-order terms to the energy and can usually be neglected. The elements diagonal in v are, of course, modified by this transformation and the effect of this transformation is to fold the elements not diagonal in v onto the v blocks.*** The matrix is illustrated in Fig. 3 where the shaded areas contain those matrix elements off diagonal in v which are transformed into the v blocks shown on the diagonal. Therefore, the infinite secular equation is effectively factored into separate blocks corresponding to various combinations of v and σ, and only one such

*** For this particular class of molecules, both H_R and H_{IR} are diagonal in K and v is the only nondiagonal index; consequently the Van Vleck transformation is identical to the ordinary perturbation treatment. However, the difference between these two methods becomes apparent for the asymmetric molecules.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

block need be considered at a time. To the second-order approximation the matrix elements of a v, σ block are given by the Hamiltonian operator[121]

$$H_{v\sigma}=A_z(P_x^2+P_y^2)+C_{v\sigma}P_z^2-2C_zP_zp_{v\sigma,v\sigma}+E_{v\sigma}, \quad (3\text{-}12)$$

where

$$p_{v\sigma,v'\sigma}=\int_0^{2\pi} U_{v\sigma}^*(\alpha)\frac{1}{i}\frac{d}{d\alpha}U_{v'\sigma}(\alpha)d\alpha,$$

$$C_{v\sigma}=C_z\left(1+4C_z\sum_v{}'\frac{|p_{v\sigma,v'\sigma}|^2}{E_{v\sigma}-E_{v'\sigma}}\right)$$

$$=C+F\rho^2\left(1+4F\sum_v{}'\frac{|p_{v\sigma,v'\sigma}|^2}{E_{v\sigma}-E_{v'\sigma}}\right),$$

$$c=\hbar^2/2I_z.$$

Here $H_{v\sigma}$ can be regarded as the effective rotational Hamiltonian for a given torsional state. The energy is then

$$E(JKMv\sigma)=A_zJ(J+1)+(C_{v\sigma}-A_z)K^2 -2C_zKp_{v\sigma,v\sigma}+E_{v\sigma}. \quad (3\text{-}13a)$$

The perturbation treatment can also be carried to higher order. The energy obtained from the nth order perturbation calculation can be expressed simply as[25a]

$$E_{v\sigma}=AJ(J+1)+(C-A)K^2 +F\sum_n w_{v\sigma}^{(n)}(\rho K)^n, \quad (3\text{-}13b)$$

where

$$\rho=I_\alpha/I_z,$$

$$w_{v\sigma}^{(0)}=9b_{v\sigma}/4,$$

$$w_{v\sigma}^{(1)}=-2p_{v\sigma,v\sigma},$$

$$w_{v\sigma}^{(2)}=1+(16/9)\sum_v{}'\frac{|p_{v\sigma,v'\sigma}|^2}{b_{v\sigma}-b_{v'\sigma}}, \text{ etc.}$$

The first two terms of Eq. (3-13b) are the energy of a rigid symmetric rotor while the last term, which is a power series in ρK, represents the effect of the internal torsion on the rotational energy levels.

The convergence of the power series depends mainly on the magnitude of ρK. Although the coefficients $w_{v\sigma}^{(n)}$ are strongly dependent on the barrier height (more precisely s) of the approximate form[99] $As^B\exp(-C\sqrt{s})$, they do not converge very rapidly with increasing n (see Fig. 8). Consequently the magnitude of the factor $(\rho K)^n$ must be examined and the perturbation calculation should then be carried out to the desired accuracy.

4. Energy levels and spectra.—For a given torsional state v there are two torsional sublevels characterized by the symmetry properties A and E (or $\sigma=0$ and ±1). Associated with each such torsional sublevel is a set of rotational energy levels, the structure of which is governed by the effective rotational Hamiltonian $H_{v\sigma}$.

For the nondegenerate A level the torsional functions are real and hence the diagonal elements of odd order in p vanish, i.e., $w_{v\sigma}^{(1)}=0$. The rotational Hamiltonian is given to the second order by the first two terms of Eq. (3-12). This is formally identical to the Hamiltonian of a rigid symmetric rotor with a modified rotational constant $C_{v\sigma}$. Consequently, the rotational levels associated with a nondegenerate A type torsional level (hereafter referred to as A rotational level or simply A levels) have the same structure as the levels of a rigid rotor (referred to also as the pseudo-rigid rotor levels). For the case of the degenerate torsional levels, $p_{v1,v1}$ is different from zero, so that the structure of the rotational levels here (called E rotational levels or E levels) differs from that of a rigid rotor. The linear term in P_z in the Hamiltonian has the effect of removing the K degeneracy characteristic of the rigid symmetric rotors. Furthermore, since the second-order perturbation term $w_{v\sigma}^{(2)}$ in Eq. (3-13b) is different for the A and E levels, each torsional sublevel will have a different effective rotational constant, $C_{v\sigma}$. The rotational levels with $\sigma=\pm1$ are doubly degenerate with respect to σ but nondegenerate with respect to K, and vice versa for the levels with $\sigma=0$. Hence, all the energy levels are doubly degenerate with the exception of the ones for which $\sigma=K=0$. Here the spatial M degeneracy has been disregarded. The three pairs of doubly degenerate levels $\sigma=0$, $\pm K$; $\sigma=+1$, $+K$; $\sigma=-1$, $-K$; and $\sigma=-1$, $+K$; $\sigma=+1$, $-K$ are shown in Fig. 4.

Physically, the presence of two sets of rotational levels with $\sigma=0$ and ±1 may be understood from a semiclassical point of view. For a high barrier the in-

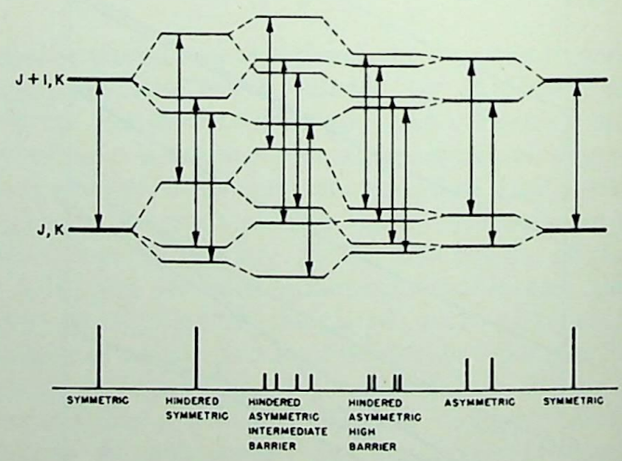

FIG. 4. Correlation of rotational energy levels. The rotational energy levels and rotational parallel ($\Delta K=0$) transitions for various conditions of asymmetry and barrier height. At either end the symmetric rotor energy levels and transition are shown. Introduction of hindered internal rotation splits each energy level in three levels for a threefold potential barrier. The three transitions however are coincident, giving only one line. Asymmetry splits the A level (K doubling), but only shifts the E levels. Two weaker lines on each side of the pattern are possible transitions between the E levels, but these are not shown in the figure. If the barrier height is raised, the energy levels tend toward the asymmetry doublets, and two doublets are observed in the spectrum. Finally, if the asymmetry is removed we are back to the symmetric rotor. The thickness of the lines for each energy level is approximately in agreement with the degeneracy of that level.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ternal motion can be pictured as a back-and-forth oscillation about the equilibrium configuration of the molecule. The over-all rotation of the molecule along with this mode of internal torsion gives rise to the set of the A levels. The E levels can be associated with a different mode of internal motion in which the molecule passes from one equilibrium configuration to another in a circulatory manner through the tunneling effect. The double degeneracy of the E torsional levels is related to the two senses (counterclockwise and clockwise) of tunneling internal rotation. One may then expect the E levels and wave functions to have some free rotational character.

As the dipole moment of the molecule is independent of α, the selection rules for the rotational transitions are $\Delta J=\pm 1, \Delta K=0$, and $\Delta\sigma=0$ (see Sec. 6). Equation (3-13) shows that the frequencies of the rotational lines are not changed by the internal rotation. Both the A and E levels give rise to the same spectral lines and the three transitions shown in Fig. 4 are all coincident. Thus the effects of the internal rotation in the symmetric molecules are not detectable in the rotational spectra associated with the ground torsional state. This result can also be understood from the classical description by noticing that the rotation of a symmetric top about its figure axis causes no change in the orientation of the dipole moment and thus no dipole interaction with the radiation. When internal rotation is present in a symmetric top molecule, only the angular velocities of the two groups along the figure axis are affected.[67] In the excited torsional states, however, the frequencies of rotational transitions are appreciably altered by the internal rotation through the interaction with the other molecular vibrations.[42] The shifts of the frequencies of these lines then serve as a means of determining the barrier heights for the symmetric top molecules. This method is more fully discussed in Sec. 7.

5. Reduction to a rigid rotor at a very high barrier.— At the limit of a very high barrier, the torsional functions can be taken as Eq. (3-11). Furthermore, the overlapping between $H_v^{(1)}$, $H_v^{(2)}$, and $H_v^{(3)}$ can be neglected, i.e., the diagonal elements of p (i.e., $w_{v\sigma}^{(1)}$) approach zero. At first sight one might conclude that the effect of H_{IR} vanishes for infinitely high barriers and the Hamiltonian is then given by H_R. This, however, is not correct because the rotational constant of P_z^2 in H_R is not the rotational constant of the rigid molecule. The reason for this is that the off-diagonal elements of p increase with the barrier height so that the second-order term

$$\sum_{v'}{}'(b_{v\sigma}-b_{v'\sigma})^{-1}|p_{v\sigma,v'\sigma}|^2$$

remains finite in such a way that $w_v^{(2)}$ tends to zero. This latter fact would be expected since Eq. (3-13b) is in the form of a rigid molecule with the actual rotation constant. With Eq. (3-11) it can be shown that the only nonvanishing matrix elements are

$$p_{v,\sigma;v+1,\sigma}=\frac{1}{\sqrt{2}i}\left(\frac{9V_3}{4F}\right)^{\frac{1}{4}}(v+\tfrac{1}{2})^{\frac{1}{2}}$$
$$p_{v,\sigma;v-1,\sigma}=-\frac{1}{\sqrt{2}i}\left(\frac{9V_3}{4F}\right)^{\frac{1}{4}}v^{\frac{1}{2}}. \tag{3-14}$$

Furthermore, the energy of a torsional harmonic oscillator was given by Eqs. (3-4) and (3-10) as

$$E_v=3(v+\tfrac{1}{2})(V_3F)^{\frac{1}{2}}=(9/4)Fb_v.$$

When this equation and Eq. (3-14) are substituted into Eq. (3-13) the second-order term $w_{v\sigma}^{(2)}$ becomes zero. Therefore, the effective rotational constant $C_{v\sigma}$ becomes the rigid rotational constant C.

B. Internal Axis Method (IAM)

The essential feature of the IAM is the application of the Nielsen transformation to remove the coupling term between the angular momentum for over-all rotation and that associated with the internal rotation. Therefore, external and internal rotation become separable for the case of symmetric molecules. The IAM, however, has the disadvantage that the torsional functions are difficult to determine and are not conveniently tabulated.

For the PAM the coupling term H_{IR} (which is not small) is reduced by the Van Vleck transformation to a power series in K whose coefficients vanish at the limit of an infinite barrier. On the other hand, the coupling term H_{IR} is removed in the IAM by the Nielsen transformation, Eq. (2-8). The difference between these two transformations is that the Van Vleck is barrier dependent while the Nielsen is barrier independent.

The Hamiltonian was given in Eq. (2-20) as

$$H=A_a(P_a'^2+P_b'^2)+C_cP_c'^2+Fp'^2+V(\alpha),$$

where

$$A_a=A_x=\hbar^2/2I_a,$$
$$C_c=C=\hbar^2/2I_z(\neq C_z).$$

The a, b, c axes are the same as the principal axes for symmetric molecules, and the differential operators for P_a', P_b', P_c', and p' are given in Sec. 2 II. C2(b). Since the P''s do not contain α, the wave function can be written as a product of the symmetric rotor wave functions and the torsional wave function:

$$\psi=S_{JKM}(\theta,\varphi)e^{iKx'}M_{Kv\sigma}(\alpha'). \tag{3-15}$$

The symmetric rotor functions are the eigenfunctions of the first three terms of the Hamiltonian Eq. (2–20) and $M_{Kv\sigma}(\alpha')$ represent the eigenfunctions of the equation

$$\left[-F\frac{d^2}{d\alpha'^2}+V(\alpha')\right]M(\alpha')=EM(\alpha'), \tag{3-16}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

with the appropriate boundary conditions. The symmetric top wave function of Eq. (3-15) contains χ' instead of χ as a variable. The angle χ' was defined in Eq. (2-15).

The boundary condition for Eq. (3-16) must now be considered. Obviously, the wave function must be periodic in 2π with respect to χ_1 and χ_2 (the Eulerian angles of the two parts), i.e.,

$$\psi(\theta,\varphi,\chi_1,\chi_2)=\psi(\theta,\varphi,\chi_1+2\pi n_1,\chi_2+2\pi n_2), \quad (3\text{-}17)$$

where n_1 and n_2 are integers. In terms of χ' and α', the wave function ψ becomes

$$\psi(\theta,\varphi,\chi',\alpha')=\psi\{\theta,\varphi,\chi'+(2\pi/I_c)[I_\alpha n_2+(I_c-I_\alpha)n_1], \alpha'+2\pi(n_2-n_1)\}. \quad (3\text{-}18)$$

In order to satisfy this condition use is made of the fact that according to Floquet's theorem, a particular (nonperiodic) solution of the Mathieu equation can be written as

$$M(\alpha)=e^{i\alpha f}P(\alpha), \quad (3\text{-}19)$$

where $P(\alpha)$ is periodic in 2π and f is a real constant which is chosen so that Eq. (3-19) has the periodicity as demanded by the physical situation. For the present case one has

$$(K/I_c)[I_\alpha n_2+(I_c-I_\alpha)n_1]+f(n_2-n_1)=n \text{ (an integer)}. \quad (3\text{-}20)$$

This can be satisfied by setting f equal to either $-\rho K$ [i.e., $-(I_\alpha K/I_c)$] or $(1-\rho)K$ [i.e., $+(I_c-I_\alpha/I_c)K$]. In the first of the series of papers on the internal rotation in methyl alcohol, Koehler and Dennison chose $(1-\rho)K$. [Also their internal angle χ is equal to $-\alpha$ which is used here (see Appendix 4).] However, it turns out, for most cases, to be convenient to take $f=-\rho K$. The resulting wave equation is then

$$\psi=S_{JKM}(\theta,\varphi)e^{iK\chi'}e^{-i\rho K\alpha'}P(\alpha'). \quad (3\text{-}21)$$

Equation (3-21) shows that the internal and external motion are separable inasmuch as the wave function can be expressed as a product of a function of the three external Eulerian angles and a function of α ($\alpha'=\alpha$) alone. The fact that the quantum number K appears in the torsional part of the wave function does not signify a physical coupling between the over-all rotation and the internal motion in the sense that the torsion of one group of the molecule about the other does not affect the motion of the "internal rotation axes" (see Sec. 2 II. A1). On the other hand, the reader may recall that in the treatment of the symmetric molecules by PAM there is a coupling term H_{IR} between the external and internal motion. In the PAM the set of moving axes is rigidly attached to one group of the molecule; while in the IAM the internal rotation axes, which are used as the coordinate system, are moving with respect to both of the groups. Since only the rotation of the internal rotation axes is unaltered by the internal motion, the coordinate frame used in PAM also oscillates at the frequency of the internal torsion.

1. Rotational equation.—The first three terms of the Hamiltonian Eq. (2-20) are the same as a rigid symmetric rotor molecule with energies as

$$H_R=A(P_a^2+P_b^2)+CP_c^2$$
$$E_{JKM}=AJ(J+1)+(C-A)K^2, \quad (3\text{-}22)$$

where

$$A=\hbar^2/2I_a \quad \text{and} \quad C=\hbar^2/2I_c.$$

2. Torsional function.—Although the torsional equations for the PAM and the IAM are identical, the torsional functions for these two cases are not the same because of the different boundary conditions. As explained above, the torsional function of IAM may be written as

$$M(\alpha)=e^{-i\rho K\alpha}P(\alpha). \quad (3\text{-}23)$$

The differential equation for $P(\alpha)$ is obtained by substituting Eq. (3-23) into Eq. (3-16) with the result

$$-F(d^2P/d\alpha^2)+2iF\rho K(dP/d\alpha)+\tfrac{1}{2}V_3(1-\cos 3\alpha)P=(E-F\rho^2K^2)P, \quad (3\text{-}24)$$

where

$$F\rho=\frac{\hbar^2}{2(I_c-I_\alpha)} \quad \text{and} \quad F\rho^2=\frac{\hbar^2}{2}\frac{I_\alpha}{I_c(I_c-I_\alpha)}.$$

This equation [or Eq. (3-16)] can be solved in the most general way by the method of continued fraction which is discussed in Appendix 2.

(*a*) *Properties of the torsional levels:* Since the solutions of Eq. (3-23) are different for different K, the value of K should be included as a labeling index for $P(\alpha)$ and E. Furthermore, as α appears explicitly in Eq. (3-16) only as $\cos 3\alpha$, an eigenfunction $M(\alpha)$ can be classified into one of the three general types corresponding to $\sigma=0,\pm1$††† in the expression

$$P_{Kv\sigma}=\sum_k A_{3k+\sigma}^{Kv}e^{i(3k+\sigma)\alpha},$$
or
$$M_{Kv\sigma}=e^{-i\rho K\alpha}\sum_k A_{3k+\sigma}^{Kv}e^{i(3k+\sigma)\alpha}. \quad (3\text{-}25)$$

Analogous to the solution of the torsional equation in the PAM, for each given σ one has a family of the functions $P_{Kv\sigma}(\alpha)$ and these functions are again labeled by the index v. Unlike the $U(\alpha)$'s given in Eq. (3-9), the eigenfunctions $P_{K,v,1}(\alpha)$ here are not degenerate with $P_{K,v,-1}(\alpha)$ because the differential Eq. (3-24) for $P(\alpha)$ contains imaginary coefficients. On the other hand, since $P^*(\alpha)$ is a solution of the equation obtained by taking the complex conjugate of Eq. (3-24) (the same

††† The quantity σ is the same as Itoh's $-\mu$ and is related to τ used by Dennison *et al.*[8,20,32,48] by the expression $K+\tau=\sigma+1$ (mod 3).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

as the differential equation for $P(\alpha)$ with $-K$), we have

$$\begin{aligned} P_{K,v,1}(\alpha) &= P_{-K,v,-1}{}^*(\alpha), \\ P_{K,v,0}(\alpha) &= P_{-K,v,0}{}^*(\alpha), \\ M_{K,v,\sigma}(\alpha) &= M_{-K,v,-\sigma}{}^*(\alpha), \\ P_{0,v,\sigma} &= U_{v,\sigma}, \end{aligned} \tag{3-26}$$

and

$$\begin{aligned} E_{K,v,1} &= E_{-K,v,-1}, \\ E_{K,v,0} &= E_{-K,v,0}. \end{aligned}$$

At high barriers the arrangement of the eigenvalues ($E_{Kv\sigma}$) in the IAM is similar to that in the PAM, i.e., the levels are grouped in a number of clusters corresponding to different values of the torsional quantum number v. Within each torsional state there are three distinct levels (rather than two in contrast with the results of the PAM) characterized by $\sigma=0, 1, -1$, for $K\neq 0$. The three levels are shown in Fig. 4. When K is equal to zero, the levels with $\sigma=1$ and $\sigma=-1$ are degenerate. The result that the eigenvalues are different for the PAM and the IAM comes as no surprise for the torsional equation is actually defined differently in these two methods. Physically, this discrepancy arises from the fact that the external rotation in the IAM is not the same as that in the PAM. However, the composite energy levels for the combination of the external and internal rotation calculated by both methods are identical as one would expect. This is illustrated in Sec. I. B3.

(*b*) *Eigenvalues of the torsional equation:* The tabulated solutions of the Mathieu equation are not directly applicable to the torsional function in the IAM since these functions do not have the periodicity of 2π. The general method for obtaining the solution by the use of continued fraction is described in Appendix 2. The procedure for determining the eigenfunctions is in general complicated but at the very high barrier these functions can be approximated by the harmonic oscillator functions. In addition, the eigenvalues can be simply obtained by the following approximate method: when $\rho K-\sigma$ is replaced by $\rho K-\sigma+3$, the form of Eq. (3-25) is not altered, and therefore the eigenvalues remain unchanged. One may then regard the eigenvalues as periodic functions of $(2\pi/3)(\rho K-\sigma)$ and expand them in a Fourier series as

$$E_{Kv\sigma}=F\sum_n a_n{}^{(v)}\cos(2\pi n/3)(\rho K-\sigma). \tag{3-27}$$

If $\rho K-\sigma$ is equal to zero or a whole multiple of three, then Eq. (3-25) reduces to the solution of the Mathieu equation (with a periodicity of π) when the substitutions given in Eq. (3-4) are made, i.e.,

$$E(\rho K-\sigma=0)\rightarrow b(\pi).$$

Here b and E differ by the scale factor given by Eq. (3-4). Similarly, one can show that

$$\begin{aligned} E(\rho K-\sigma=\tfrac{3}{2}) &\rightarrow b(2\pi), \\ E(\rho K-\sigma=1) &\rightarrow b(3\pi), \end{aligned}$$

and more generally

$$E(\rho K-\sigma=x)\rightarrow b(3\pi/x).$$

Up to this time only the low integral values of $3/x$ have been tabulated (see Appendix 3).

If the series in Eq. (3-27) converges so rapidly that E may be approximated by the first two terms in the Fourier expansion, i.e.,

$$E=F[a_0+a_1\cos(2\pi/3)(\rho K-\sigma)], \tag{3-28}$$

then the coefficients a_0 and a_1 may be determined from the tabulated values[104] of $b(\pi)$ and $b(2\pi)$. When this is done, Eq. (3-28) can be used to calculate the approximate values of $b(N\pi)$. To this approximation the equation for $b(N\pi)$ is

$$b(N\pi)=\frac{1}{2}\left(1+\cos\frac{2\pi}{N}\right)b(\pi) + \frac{1}{2}\left(1-\cos\frac{2\pi}{N}\right)b(2\pi), \tag{3-29}$$

such that any Mathieu eigenvalue can be approximated[23] from $b(\pi)$ and $b(2\pi)$ provided that the Fourier coefficient a_1 is small. If the coefficient a_1 is not small then $b(3\pi)$, $b(4\pi)$, etc., can be used to obtain the coefficients a_2 and a_3 and a better value of $b(N\pi)$ (see Table III). Therefore, the Mathieu eigenvalues can be readily approximated for any periodicity.

(*c*) *Harmonic oscillator approximation:* As in the case of the PAM, the torsional function can be approximated by harmonic oscillator wave functions at very high barriers. Since the classical amplitude of the internal torsion approaches zero at the limit of very high barriers, the factor $e^{-i\rho K\alpha}$ in the torsional function $M(\alpha)$ may be replaced by unity and $M_{Kv\sigma}(\alpha)\rightarrow P_{Kv\sigma}(\alpha)$. Under such circumstances $M(\alpha)$ can be approximated by Eq. (3-11). The energy levels of Eq. (3-16) are then given by Eq. (3-10).

3. Energy levels and spectra.—The total energy of a symmetric top exhibiting internal rotation is equal to the sum of the energy associated with the over-all rotation E_{JKM} and the torsional energy $E_{Kv\sigma}$, or

$$E(JKMv\sigma)=E_{JKM}+E_{Kv\sigma}. \tag{3-30}$$

Since the K degeneracy remains in the rigid symmetric rotor energy, from Eq. (3-26) it may be seen that

$$E(J,K,M,v,\sigma)=E(J,-K,M,v,-\sigma).$$

Therefore, all the energy levels are doubly degenerate except the $K=0, \sigma=0$ levels—a result which was also found by the PAM. Now substituting Eqs. (3-22) and (3-27) into Eq. (3-30), we obtain

$$E(JKMv\sigma)=AJ(J+1)+(C-A)K^2 + F\sum_n a_n{}^{(v)}\cos\frac{2\pi n}{3}(\rho K-\sigma). \tag{3-31a}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The last term in this equation represents the effect of the internal torsion on the rotational energy levels. If ρK is reasonably small and the Fourier series converges rapidly, the cosine terms in the last member of Eq. (3-31) can be expanded in the following manner:

$$\sum a_n^{(v)} \cos\frac{2\pi n}{3}(\rho K-\sigma)$$

$$=\sum_n a_n^{(v)} \cos\frac{2\pi\sigma}{3}\left[1-\frac{1}{2}\left(\frac{2\pi n}{3}\rho K\right)^2+\cdots\right]$$

$$+\sum a_n^{(v)} \sin\frac{2\pi\sigma}{3}\left[\frac{2\pi n}{3}\rho K+\cdots\right]. \quad (3\text{-}31b)$$

For $\sigma=0$ the K^2 term from Eq. (3-31b) can be incorporated into the term $(C-A)K^2$ in Eq. (3-31a), and therefore it has the effect of modifying the rotational constant. The rotational levels for this case have the same pattern as a rigid symmetric rotor—pseudo-rigid rotor level. In the case of the degenerate torsional levels ($\sigma=\pm1$), the expansion in Eq. (3-31b) introduces a term linear in K, into the energy equation. This causes a splitting of the K degeneracy of the rigid symmetric rotors. The conclusions obtained here are therefore in complete agreement with those derived from the PAM. When ρK becomes larger, the $(\rho K)^3$ and $(\rho K)^4$ terms should be included in the expansion of $\cos(2\pi/3)(\rho K-\sigma)$. In terms of the PAM the higher-order Van Vleck perturbation treatment must be applied to the Hamiltonian in order to obtain accurate results.

By following the selection rules $\Delta J=\pm1$, $\Delta K=0$, and $\Delta\sigma=0$ one finds again that the rotational frequencies depend only on the rotational constant A and the quantum number J, and are not affected by the internal torsion. Therefore, only one line is observed as shown in Fig. 4 for this model.

C. Comparison of the Two Methods

The main difference between the two methods is that the IAM gives a relatively simple Hamiltonian but more complicated torsional functions, whereas the PAM gives a more complex Hamiltonian but simpler torsional functions. The chief difficulty in the IAM is associated with the determination of the torsional eigenfunctions and eigenvalues. On the other hand, the coupling term pP_z in the PAM is not a small perturbation, so fourth-order perturbation calculation is sometimes necessary to obtain accurate results for the energy levels.

A comparison of Eqs. (3-13b) and (3-31a) shows that the effects of the internal torsion on the rotational energy levels are expressed by a power series in the PAM and a Fourier series in the IAM. Generally, calculation of the first- and second-order terms in the power series ($w_{v,\sigma}^{(1)}$ and $w_{v,\sigma}^{(2)}$) is comparatively simple, but the higher-order terms are more difficult to evaluate. Herschbach[23] has suggested that the tabulated eigenvalues of the Mathieu equation and the first two perturbation terms in PAM be used to determine the Fourier coefficients in the IAM which are otherwise tedious to calculate by the method of continuous fraction. Since the Fourier series in IAM converges much faster than the power series in Eq. (3-13b), the former may be used to obtain the rotational energy levels and also the higher-order perturbation terms of the PAM. This technique is really very interesting for we have solved the problem approximately by the PAM where the boundary conditions are simple and have then converted this to the more exact solution of the IAM.

II. Asymmetric Molecules

A. *Principal Axis Method* (PAM)

The Hamiltonian given in Eq. (2-37) can be grouped in the following manner:

$$H_0=\tfrac{1}{2}(A_x+B_x)(P_x^2+P_y^2)+C_zP_z^2+Fp^2+V(\alpha), \quad (3\text{-}32a)$$

$$H_1=-2\sum_i Q_iP_ip, \quad (3\text{-}32b)$$

and

$$H_2=\tfrac{1}{2}(A_x-B_x)(P_x^2-P_y^2)$$
$$+\tfrac{1}{2}\sum_{i\neq j} D_{ij}(P_iP_j+P_jP_i). \quad (3\text{-}32c)$$

The energy matrix is now constructed with the basis functions

$$S_{JKM}(\theta,\varphi)e_i^{Kx}U_{v\sigma}(\alpha).$$

In this representation H_0 is completely diagonal; H_2 is diagonal in v, but not in K; and H_1 has diagonal and off-diagonal matrix elements in K and v. As in the case of symmetric molecules, the Van Vleck transformation is applied to remove the nondiagonal elements in v so that the new energy matrix assumes the block structure shown in Fig. 3. The effective rotational Hamiltonian, correct to second order, for the vth torsional state is‡‡‡

$$H_{v\sigma}=A_{v\sigma}P_x^2+B_{v\sigma}P_y^2+C_{v\sigma}P_z^2+E_{v\sigma}$$
$$+\tfrac{1}{2}\sum_{i\neq j} D_{ij}w_{v\sigma}^{(2)}(P_iP_j+P_jP_i)+\sum_i Q_iP_iw_{v\sigma}^{(1)}, \quad (3\text{-}33)$$

where

$$A_{v\sigma}=\frac{h^2}{2I_x}\left[1+\frac{\lambda_x^2I_\alpha}{rI_x}w_{v\sigma}^{(2)}\right],$$

$$w_{v\sigma}^{(1)}=-2p_{v\sigma,v\sigma},$$

$$w_{v\sigma}^{(2)}=1+\frac{16}{9}\sum_{v'}{}'\frac{|p_{v\sigma,v'\sigma}|^2}{b_{v\sigma}-b_{v'\sigma}},$$

‡‡‡ Here we have assumed that the torsional levels of different v are much more widely spaced compared to the rotational levels. When this is not the case, the $(K|K')$ elements, introduced by H_1 to the diagonal v blocks through the Van Vleck transformation, have a very complicated form.[25b]

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and similarly for B_v and C_v with the appropriate permutations of x, y, and z.

Alternatively the Hamiltonian given in Eq. (2-38) could be used for the perturbation treatment. The Van Vleck transformation now gives the following[23]:

$$H_{v\sigma}=\frac{h^2}{2}\sum_g\frac{P_g^2}{I_g}+F\sum_n w_{v\sigma}^{(n)}\Pi^n, \qquad (3\text{-}34)$$

where

$$\Pi=\varrho\cdot\mathbf{P},$$

and the $w_{v\sigma}^{(n)}$'s are the same perturbation terms given in Eq. (3-13b). Naturally, Eqs. (3-33) and (3-34) are identical. Equation (3-33) shows the perturbation calculation more clearly and shows that the rotational constants are modified by the internal rotation. Equation (3-34) shows the similarity to the symmetric molecule formulas and leads more naturally, as we will see later, to higher-order perturbation corrections.

1. Energy levels and spectra.—From Eq. (3-33) the rotational constants for the over-all rotation of the molecule are modified by the internal rotation. Also the orientation of the "effective" principal axes is changed by the cross terms $D_{ij}w_{v\sigma}^{(2)}(P_iP_j+P_jP_i)$. Both of these changes depend on the torsional state v and σ. As in the case of the symmetric molecules, there exist two sets of rotational levels for each torsional state. The Hamiltonian for the pseudo-rigid rotor levels ($\sigma=0$) to second order is given by Eq. (3-35),

$$H_{v0}=A_{v0}P_x^2+B_{v0}P_y^2+C_{v0}P_z^2+\sum_{i\neq j}\tfrac{1}{2}D_{ij}w_{v0}^{(2)}(P_iP_j+P_jP_i), \qquad (3\text{-}35)$$

where the rotational constants A_{v0}, etc., differ from the respective constants of a rigid molecule by terms proportional to $w_{v0}^{(2)}$. Also the cross terms between the P's contain $w_{v0}^{(2)}$. As mentioned before, the quantity $w_{v0}^{(2)}$ decreases rapidly with increasing value of the reduced barrier height s [defined in Eq. (3-4)] and approaches zero for very high barrier.

For the E levels the Hamiltonian is also given by Eq. (3-33). Because of the linear terms in P_x, P_y, and P_z the spacings of the E levels are different even qualitatively from those of a pseudo-rigid rotor. However, in some cases, especially for high barriers and low K energy levels, when the asymmetry splitting of the K doublet is not too small, the effect of the terms containing $p_{v\sigma,v\sigma}$ is negligible.§§§ The effective rotational constants $A_{v,\pm1}$, etc., are, however, appreciably different from those for the A states as well as those for the rigid molecule. Under such circumstances both sets of the A and E levels are similar in structure but have different effective rotational constants.

§§§ It should be noted that the effect of the linear terms is negligible only when it connects no near degenerate levels. Also if the quantity ρK becomes large, higher-order perturbation terms are needed [see Eq. (3-34) and Sec. 3].

The selection rules are identical to those for a rigid asymmetric top with the additional restriction of $\Delta\sigma=0$ since the dipole moment is independent of the angle α. The most intense spectrum arises from the molecules in the lowest torsional state, i.e., $v=0$. For each rotational transition one finds two lines; one originates from the rotational levels associated with the nondegenerate torsional levels and the other one from the degenerate E levels. The essential feature of the spectrum is that doublets occur instead of a single line as in the case of a rigid molecule. This is illustrated in Fig. 4. The lines belonging to the A species follow a pseudo-rigid spectrum to the second order and the E lines may or may not be fitted to a pseudo-rigid Hamiltonian depending on the height of the barrier and the asymmetry of the molecule. The two members of the doublet are of more or less the same intensity; the ratio of the intensity is governed by the relative nuclear statistical weight assigned to the A and E levels (see Sec. 6). The separation of the two lines of a doublet depends very critically on the height of the barrier. It is from these splittings that we determine the barrier height. In the next section we discuss the calculation of the doublet splittings. The methods of evaluation of the barrier height from the measured values of the splittings are presented in Sec. 5.

2. Calculation of energy and doublet splittings.—The matrix elements of $H_{v\sigma}$ in Eq. (3-33)[101] are

$$\begin{aligned}
(K|H_{v\sigma}|K)&=\tfrac{1}{2}(A_{v\sigma}+B_{v\sigma})J(J+1)\\
&\quad+[C_{v\sigma}-\tfrac{1}{2}(A_{v\sigma}+B_{v\sigma})]K^2+Q_zw_{v\sigma}^{(1)}K,\\
(K|H_{v\sigma}|K\pm1)&=\tfrac{1}{2}[(D_{yz}\pm iD_{xz})w_{v\sigma}^{(2)}(2K\pm1)\\
&\quad+(Q_y\pm iQ_x)w_{v\sigma}^{(1)}][J(J+1)-K(K\pm1)]^{\frac{1}{2}},\\
(K|H_{v\sigma}|K\pm2)&=-\tfrac{1}{4}[A_{v\sigma}-B_{v\sigma}\pm2iD_{xy}w_{v\sigma}^{(2)}]\\
&\quad\times[J(J+1)-K(K\pm1)]^{\frac{1}{2}}\\
&\quad\times[J(J+1)-(K\pm1)(K\pm2)]^{\frac{1}{2}}. \qquad (3\text{-}36)
\end{aligned}$$

The indices J, M have been deleted since $H_{v\sigma}$ is diagonal in these quantum numbers, and the constant term $E_{v\sigma}$ has been dropped. Here, in addition to the $(K|K\pm2)$ contribution from the usual asymmetry of H_2, there are off-diagonal elements from the cross terms in $D_{ij}w_{v\sigma}^{(2)}$. Also H_1 has contributed both a diagonal term in $Q_zw_{v\sigma}^{(1)}$ and off-diagonal terms in $Q_xw_{v\sigma}^{(1)}$ and $Q_yw_{v\sigma}^{(1)}$.

The Hamiltonian $H_{v\sigma}$ in Eq. (3-33) may be simplified by performing a rotation of coordinate axes to eliminate the cross terms between the components of the total angular momentum P. Referred to this new coordinate axes system which is the "effective principal axes" system for a torsional level, the effective Hamiltonian becomes

$$H_{v\sigma}'=A_{v\sigma}'P_x'^2+B_{v\sigma}'P_y'^2+C_{v\sigma}'P_z'^2+\sum_i Q_i'P'w_{v\sigma}^{(1)}. \qquad (3\text{-}37)$$

The orientation between the two sets of axes can be determined either by diagonalizing the 3×3 matrix in

TABLE I. Low J energy levels.[a]

E_{JK}

$E_{00}=0$

$E_{10}=A_{v\sigma}'+B_{v\sigma}'-(g^{+}+g^{-})$

$E_{11}=\frac{1}{2}(A_{v\sigma}'+B_{v\sigma}')+C_{v\sigma}'+\frac{1}{2}(g^{+}+g^{-})$
$\pm[(Q_x'w_v^{(1)})^2+\frac{1}{4}(A_{v\sigma}'-B_{v\sigma}')^2-(A_{v\sigma}'-B_{v\sigma}')(g_y-g_x)]^{\frac{1}{2}}$

$E_{20}=W_r(A_{v\sigma}'B_{v\sigma}'C_{v\sigma}'J=2, K=0)-3(g^{+}+g^{-})$
$+0[(A-B)(2C-A-B)^{-1}g]$

$E_{21}=(5/2)(A_{v\sigma}'+B_{v\sigma}')+C_{v\sigma}'+3(g^{+}+g^{-})/2-(k^{+}+k^{-})$
$\pm[(Q_z'w_v^{(1)})^2+(9/4)(A_{v\sigma}'-B_{v\sigma}')^2-9(A_{v\sigma}'-B_{v\sigma}')(g_y-g_x)]^{\frac{1}{2}}$

where

$g^{\pm}=(Q_x'^2+Q_y'^2)[w_{v\sigma}^{(1)}]^2[2C_{v\sigma}'-A_{v\sigma}'-B_{v\sigma}'\pm 2Q_z'w_{v\sigma}^{(1)}]^{-1}$

$g_i=Q_i'^2[w_{v\sigma}^{(1)}]^2[2C_{v\sigma}'-A_{v\sigma}'-B_{v\sigma}']^{-1}(i=x, y)$

$g_x+g_y\approx\frac{1}{2}(g^{+}+g^{-})$

$k^{\pm}=2(Q_x'^2+Q_y'^2)[w_{v\sigma}^{(1)}]^2[6C_{v\sigma}'-3A_{v\sigma}'-3B_{v\sigma}'\pm 2Q_z'w_{v\sigma}^{(1)}]^{-1}$

[a] The $A_{v\sigma}'$, $B_{v\sigma}'$, and $C_{v\sigma}'$ are not necessarily identical with the A, B, and C of King *et al.*,[41] and the quantum number K is no longer a good quantum number, but it is still used for labeling. In the expression for the E_{20} energy W_r is the rigid rotor energy with the rotational constants A_v', B_v', and C_v'.

the usual manner or by applying successive 2×2 rotations. The relations between the new coefficients $A_{v\sigma}'$, etc., in Eq. (3-37) and the old ones in Eq. (3-33) can be set down by noting that A, B, C, D_{xy}, etc., transform like the six components of a symmetric second-rank tensor and Q_x, Q_y, Q_z, transform like the components of a vector. Very often the change in the effective rotational constants introduced by such a rotation is negligible. For instance, in the case of acetaldehyde (CH_3CHO) the cross term P_iP_j is removed by rotating the body axes through an angle of approximately one degree.

For the nondegenerate A levels the last term of Eq. (3-37) vanishes. The rotational energies are just those for a pseudo-rigid rotor with slightly corrected rotational constants and can be calculated by well-known methods or obtained from published tables.[41,97,108] In the case of the E levels the energy matrices for both Eq. (3-33) and Eq. (3-37) contain a term linear in K on the diagonal and also $(K|K\pm1)$ elements. The two kinds of factoring available for rigid asymmetric tops are spoiled, and for a given J, a $(2J+1)(2J+1)$ determinantal equation must be solved. Except for low J, the straightforward diagonalization of this matrix is very difficult. The procedure of diagonalization may be somewhat simplified by applying a Van Vleck transformation to reduce the $(K|K\pm1)$ elements. Except for the energy levels with small asymmetry splitting, after a second-order Van Vleck transformation the new $(K|K\pm1)$ elements are usually such that their contributions to the diagonal terms are negligible for low J levels. The approximate formulas for some of the energy levels are given in Table I. Also approximate formulas for the splitting of the A and E levels (not the lines) can be derived; these are given in Table II.

When the barrier is very high the value of $w_{v\sigma}^{(1)}$ becomes so small that the E levels for low K also conform to the pattern of a rigid rotor with effective rotational constants different from those belonging to the A levels. The energy splitting between the A and E levels, ΔW, is simply equal to the difference between the "rigid rotor energy" of the two types of levels, W_A, and W_E, as

$$\Delta W=W_A-W_E=(\partial W/\partial A)\Delta A+(\partial W/\partial B)\Delta B+(\partial W/\partial C)\Delta C. \quad (3\text{-}38)$$

If the rigid rotor energy is written in the usual form[41]

$$W=\tfrac{1}{2}(A+C)J(J+1)+\tfrac{1}{2}(A-C)E(\kappa),\|\|\| \quad (3\text{-}39)$$

then it follows that

$$\begin{aligned}\partial W/\partial A&=\tfrac{1}{2}J(J+1)+\tfrac{1}{2}E(\kappa)-\tfrac{1}{2}(\kappa+1)[\partial E(\kappa)/\partial\kappa],\\ \partial W/\partial B&=\partial E(\kappa)/\partial\kappa,\\ \partial W/\partial C&=\tfrac{1}{2}J(J+1)-\tfrac{1}{2}E(\kappa)+\tfrac{1}{2}(\kappa-1)[\partial E(\kappa)/\partial\kappa].\end{aligned} \quad (3\text{-}40)$$

The values of $[\partial E(\kappa)/\partial\kappa]$ can be estimated from the tabulated eigenvalues of rigid rotors.[41,108] By substituting the results of Eq. (3-40) into Eq. (3-38) the energy separation between the A and E levels is obtained.

3. Higher-order effects.—(a) Third- and fourth-order perturbation terms[23,25b]: Up to this point the discussion of the PAM represents the second-order theory in the Van Vleck perturbation treatment. When the barrier is not sufficiently high and/or the quantity ρK is large (as in the case of CH_3COOH),[105] the third- and fourth-order perturbation terms should be taken into consideration. The form of the effective Hamiltonian given in Eq. (3-34) is very convenient for the calculation of the higher-order terms. Also, the perturbation coefficients are the same as those given in Eq. (3-13b) for a symmetric molecule. The higher-order perturbation corrections can be calculated directly from the matrix elements of p or by the labor-saving method given in Sec. I. C. Herschbach[23,25b] has tabulated a number of these terms. The readers are directed to Sec. 5 for more detail of this method. With the higher-order terms,

TABLE II. Low J energy splitting $(A-E)$.

$\Delta E_{00}=0$

$\Delta E_{10}=\Delta A+\Delta B+g^{+}+g^{-}$

$\Delta E_{11}=\Delta C+\frac{1}{2}(\Delta A+\Delta B)-\frac{1}{2}(g^{+}+g^{-})$
$\pm\left[\frac{1}{2}(\Delta A-\Delta B)+(g_y-g_x)-\frac{Q_z^2[w_{v\sigma}^{(1)}]^2}{A-B}\right]$

$\Delta E_{21}=\Delta C+(5/2)(\Delta A+\Delta B)-(3/2)(g^{+}+g^{-})+(k^{+}+k^{-})$
$\pm\left[(3/2)(\Delta A-\Delta B)+3(g_y-g_x)-\frac{Q_z^2[w_{v\sigma}^{(1)}]^2}{3(A-B)}\right]$

where

$$|Q_zw_{v\sigma}^{(1)}|<|(A-B)|$$

$\|\|\|$ In this equation the rotation constants A, B, C, are such that $A\geq B\geq C$ and they are not necessarily identical to $A_{v\sigma}$, $B_{v\sigma}$, and $C_{v\sigma}$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

matrix elements of the form $(K|K\pm3)$ and $(K|K\pm4)$ are introduced and these can be treated in a manner similar to Kivelson and Wilson's treatment[47] of the centrifugal distortion problem.

(*b*) *Sixfold potential energy term*, V_6[25b,38]: So far we have assumed that the potential function is sinusoidal in α without rigorous justification. If the expansion of the potential function in Eq. (2-1b) converges rapidly, the V_6 term can be treated as a perturbation. When this is done, the V_6 contribution merely changes the values of all the perturbation coefficients $w_{v\sigma}^{(n)}$ in such a way that its contribution cannot be separated from that of V_3 without data from more than one torsional state. In order to evaluate the V_6 coefficient, it is necessary then to study the internal rotational effects in more than one torsional state.¶¶¶ This V_6 term should be generally smaller than the threefold potential by a factor ranging from ten to a thousand.

B. Internal Axis Method (IAM)

Since the treatment by the IAM for the most general type of molecule (no symmetry aside from that of the CH_3 group) is algebraically very complicated, the discussion here is confined to those molecules which have a planar framework. Papers by Pitzer and Gwinn,[84] Hecht and Dennison,[20] and Burkhard[7] discuss the general type of asymmetric molecule by the IAM.

1. Hamiltonian and matrix elements.—In Sec. 2 three different forms of the Hamiltonian were derived. They were given in Eqs. (2-26), (2-29), and (2-31). We are now at liberty to use any one of these Hamiltonians to solve for the energy levels. Let us first consider the Hamiltonian (2-29).[20,31] This Hamiltonian can be divided as follows:

$$H_0=\tfrac{1}{2}(A_a+B_b'')(P_a''^2+P_b''^2)+C_c''P_c''^2+Fp'^2+V(\alpha),$$
$$H_1=\tfrac{1}{2}(A_a-B_b'')(P_a''^2-P_b''^2)+D_{bc}''(P_b''P_c''+P_c''P_b'').$$

P_a'', P_b'', and P_c'' are the components of the total angular momentum along the axes fixed in the framework of the molecule (rather than the internal axes which rotate with respect to both the framework and the top), i.e., the orientation of this axes system is described by the Eulerian angles θ, Φ, and χ (but not χ'). Consequently, we choose the eigenfunctions of H_0 as the basis functions for constructing the energy matrix. These functions are

$$\psi=S_{JKM}(\theta,\Phi)e^{iK\chi}Q(\alpha), \tag{3-41}$$

where $Q(\alpha)$ is the solution of the torsional equation

$$[Fp'^2+V(\alpha)]Q(\alpha)=EQ(\alpha). \tag{3-42}$$

Since P_c'' is diagonal in H_0, using Eq. (2-28) we can write

$$p'=p-\rho P_c''=(1/i)(\partial/\partial\alpha)_{\theta,\Phi,\chi}-\rho K, \tag{3-43}$$

which can then be substituted into Eq. (3-42) with the result

$$[F(-i(d/d\alpha)-\rho K)^2+V(\alpha)]Q(\alpha)=EQ(\alpha), \tag{3-44a}$$

or

$$[-F(d^2/d\alpha^2)+V(\alpha)]M(\alpha)=EM(\alpha), \tag{3-44b}$$

where $M(\alpha)$ is $e^{-i\rho K\alpha}Q(\alpha)$. Equations (3-44) are just the same as Eqs. (3-16) and (3-24) only with the scale change in ρ and F [see Eq. (2-30)]. Analogous to the function $P(\alpha)$ in Eq. (3-25) the eigenfunction $Q(\alpha)$ can be expanded in a Fourier series as

$$Q(\alpha)=\sum_k A_{3k+\sigma}{}^{Kv}e^{i(3m+\sigma)\alpha}. \tag{3-45}$$

Furthermore, it can be easily seen that

$$Q_{Kv\sigma}(\alpha)=Q_{-Kv-\sigma}{}^*(\alpha),$$
$$E_{Kv\sigma}=E_{-Kv-\sigma}. \tag{3-46}$$

Before deriving the matrix elements of H let us consider the Hamiltonian[20] given in Eq. (2-31). This Hamiltonian can be divided as follows:

$$H_0=\tfrac{1}{2}(A_a+B_b'')(P_a'^2+P_b'^2)+C_c''P_c'^2+Fp'^2+V(\alpha)$$
$$H_1=\tfrac{1}{2}(A_a-B_b'')$$
$$\times[(P_a'^2-P_b'^2)\cos2\rho\alpha-(P_a'P_b'+P_b'P_a')\sin2\rho\alpha]$$
$$+D_{bc}''[(p_b'p_c+P_c'P_b')\cos\rho\alpha$$
$$+(p_a'P_c'+P_c'P_a')\sin\rho\alpha]. \tag{3-47}$$

Here P_a', P_b', and P_c' are components of the total angular momentum along the internal rotational axes. The orientation of this axes system is described by the Eulerian angles $\theta\Phi\chi'$ where

$$\chi'=\chi+\rho\alpha,$$

[see Eq. (2-28)]. The basis functions again are chosen to diagonalize H_0. They are

$$\psi=S_{JKM}(\theta,\Phi)e^{iK\chi'}M(\alpha'), \tag{3-48}$$

where $M(\alpha')$ is the solution of the torsional equation (3-44b) which must satisfy the boundary conditions [see Eq. (3-20) Sec. I. B]. Furthermore, we can see that the basis functions given in Eqs. (3-41) and (3-48) are indeed identical as

$$e^{iK\chi}Q(\alpha)=e^{iK\chi'}e^{-i\rho K\alpha}Q(\alpha)=e^{iK\chi'}M(\alpha').$$

The energy matrix can then be constructed from the Hamiltonian Eq. (2-29) with Eq. (3-41) as the basis functions or from Eqs. (2-31) and (3-48). The results of these two schemes are identical.

The matrix elements of the Hamiltonian[20,31] are as follows:

$$(Kv\sigma|H|Kv\sigma)=\tfrac{1}{2}(A_a+B_b'')[J(J+1)-K^2]$$
$$+C_c''K^2+E_{Kv\sigma}, \tag{3-49a}$$

¶¶¶ Kilb *et al.*[38] calculated a V_6 term but their approximation is now realized to be inadequate because they ignored the third-order correction in the evaluation of the V_6 term from the splittings in the ground torsional states.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$$(Kv\sigma|H|K+1, v'\sigma)=D_{bc}''(K+\tfrac{1}{2})\times[J(J+1)-K(K+1)]^{\frac{1}{2}}I_{K+1,v'\sigma}{}^{Kv\sigma}, \quad (3\text{-}49b)$$

$$(Kv\sigma|H|K+2, v'\sigma)=-\tfrac{1}{4}(A_a-B_b'')[J(J+1)-K(K+1)]^{\frac{1}{2}}\times[J(J+1)-(K+1)(K+2)]^{\frac{1}{2}}I_{K+2,v'\sigma}{}^{Kv\sigma}, \quad (3\text{-}49c)$$

where

$$I_{K'v'\sigma}{}^{Kv\sigma}=\int_0^{2\pi} Q_{Kv\sigma}{}^*(\alpha)Q_{K'v'\sigma}(\alpha)d\alpha.^{****} \quad (3\text{-}50)$$

If the Hamiltonian form given in Eq. (2-26) were to be used,[8,31] then the scale factors ρ and F would be those corresponding to the symmetric molecule, i.e., $\rho=I_\alpha/I_{cc}$ and $F=(\hbar^2/2)[I_{cc}/I_\alpha(I_{cc}-I_\alpha)]$. Unfortunately, there are more matrix elements (those linear in p') which needed to be calculated and generally this formulation has no advantage over the other two. As a result we do not discuss it further.

2. Integrals involving the torsional functions.[20]—In order to obtain the energy levels it is necessary first to compute the integrals given in Eq. (3-50). Evaluation of such integrals is generally quite complicated because of the difficulty involved in the determination of the torsional functions by the procedure of continued fractions. Fortunately, for the case of high barriers ($s\gtrsim 20$), one may use the harmonic oscillator approximation for the torsional functions and the integrals can be obtained in a much simpler way.

At the limit of infinite barrier, $I_{K'v'\sigma}{}^{Kv\sigma}$ approaches zero for $v\neq v'$ and unity for $v=v'$. It is convenient then to introduce the terms

$$\delta_{K+1,v\sigma}{}^{Kv\sigma}=1-\int_0^{2\pi} Q_{Kv\sigma}{}^*(\alpha)Q_{K+1,v\sigma}(\alpha)d\alpha,$$
$$\delta_{K+2,v\sigma}{}^{Kv\sigma}=1-\int_0^{2\pi} Q_{Kv\sigma}{}^*(\alpha)Q_{K+2,v\sigma}(\alpha)d\alpha. \quad (3\text{-}51)$$

By using the harmonic oscillator approximation for the torsional wave function Hecht and Dennison[20] obtained the following formulas for the ground torsional state $v=0$:

$$\delta_{K+1,0\sigma}{}^{K0\sigma}=f(\rho/3),$$
$$\delta_{K+2,0\sigma}{}^{K0\sigma}=f(2\rho/3), \quad (3\text{-}52)$$

where

$$f(x)=\frac{1}{\sqrt{s}}x^2+\frac{1}{2s}x^2(1-x^2)+\cdots.$$

Expressions for $I_{K'v'\sigma}{}^{Kv\sigma}(v\neq v')$ have also been derived by Hecht and Dennison from the harmonic oscillator approximation [see Eq. (28) of reference 20]. An important property of the integrals in Eq. (3-50) is their relative independence of the quantum numbers K and σ. Furthermore, unlike the case of PAM the matrix elements off-diagonal in v are usually very small and their contributions to the energy are rather unimportant.

3. Diagonalization of the energy matrix.—The diagonalization of those elements off-diagonal in v can be accomplished by a Van Vleck transformation. After this transformation the energy matrix takes on a block structure in which each block corresponds to a certain value of J with the dimensions $(2J+1)\times(2J+1)$. Both $(K|K\pm1)$ and $(K|K\pm2)$ elements are present in these submatrices because the coordinate axes are not principal axes. One then applies a transformation S $(=S_1S_2)$ which diagonalizes the limiting rigid rotor Hamiltonian. The off-diagonal elements of the transformed Hamiltonian now consist of only the terms containing the integrals $I_{K'v'\sigma}{}^{Kv\sigma}$ and $E_{Kv\sigma}$. Examples of the transformed Hamiltonian have been given by Hecht and Dennison for $J=1$.†††† The energy levels can then be obtained by the usual perturbation method (or a modified procedure may be recommended in case near degeneracy occurs). One may, of course, apply a transformation S' to H to bring it directly into the diagonal form. The advantage of using S instead of S' is that the former transformation matrix can be set down in a systematic fashion.

Let S be written as S_1S_2 where S_1 transforms the coordinate axes to the principal axes system and S_2 is the matrix which diagonalizes the asymmetric rigid-rotor Hamiltonian (referred to principal axes) in the symmetric top representation. The elements of S_2 can be determined from the asymmetric rotor energy levels by well-known techniques.[97] The elements of S_1 can be written directly from the representation of the rotational group as given by Wigner[117] as

$$\psi_{JK_p}=\sum_K D^J(\beta)_{K_pK}\psi_{JK}=\sum_K(S_1)_{K_pK}\psi_{JK}, \quad (3\text{-}53)$$

where K_p and K refer to the quantum number along the z principal axis and the internal axis, respectively, and

$$D^J(\beta)_{K_pK}=\sum(-1)^n \times\frac{[(J+K)!(J-K)!(J+K_p)!(J-K_p)!]^{\frac{1}{2}}}{(J-K_p-n)!(J+K-n)!n!(n+K_p-K)!}\times\left(\cos\frac{\beta}{2}\right)^{2J+K-K_p-2n}\left(\sin\frac{\beta}{2}\right)^{2n+K_p-K}. \quad (3\text{-}54)$$

The summation is from the larger of 0 or $(K-K_p)$ to the smaller of $(J-K)$ or $(J-K_p)$. The angle β is the angle between the vector ϱ and z principal axis, i.e.,

**** Hecht and Dennison[20] chose the torsional function in the form of $M_{Kv\sigma}(\alpha)=e^{i(1-\rho)K\alpha}Q_{Kv\sigma}(\alpha)$, which leads to the same integrals $I_{K'v'\sigma}{}^{Kv\sigma}$ in different forms. The form given above is the same as Itoh's.[31]

†††† See p. 38 of reference 20. In these matrices the elements nondiagonal in v have been neglected because they do not contribute to the splittings of the A and E levels but only cause a shift in frequencies.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the angle between the c' and the z axis:

$$\sin\beta=\rho_y/\rho.$$

For small angles of β Eq. (3-54) can be expanded (to the order of β^2) with the results[62]:

$$(S_1)_{KK}=1-\frac{\beta^2}{4}[J(J+1)-K^2],$$

$$-(S_1)_{K,K+1}=+(S_1)_{K+1,K}=\frac{\beta}{2}[(J-K)(J+K+1)]^{\frac{1}{2}}, \tag{3-55}$$

$$(S_1)_{-1,1}=(S_1)_{1,-1}=\frac{\beta^2}{8}J(J+1),$$

$$(\beta\approx\rho_y/\rho,\ \alpha\approx\rho_z/\rho).$$

4. Energy levels and spectra.—Since the energy matrix given in Eq. (3-49) is diagonal in σ, one may expect to have three series of energy levels corresponding to $\sigma=0$, 1, -1. From Eq. (3-46) the energy submatrices for $\sigma=1$ and $\sigma=-1$ are identical, therefore the energy levels for $\sigma=\pm1$ are doubly degenerate. The eigenfunctions for $\sigma=\pm1$ correspond to the symmetry species E of the C_3 group, and the levels with $\sigma=0$ have the symmetry properties of the A species. Since v is nearly a good quantum number (the elements off-diagonal in v are small), a torsional level is labeled by v and σ, and associated with each torsional level one has a set of rotational energy levels characterized by the quantum numbers J, K, M.

The selection rules $\Delta\sigma=0$ (derived in Sec. 6) predict two lines for each rotational transition associated with the ground torsional state $v=0$ for relatively high barriers, one from the nondegenerate torsional levels $\sigma=0$, and one from $\sigma=\pm1$. Figure 4 shows two pairs of such transitions arising from the two K doublets of a slightly asymmetric top. The splitting of the doublets depends mainly on the tunneling, and the separation between the two pairs of doublets depends on the asymmetry. When the splitting and the separation become comparable in magnitude a mixing of states occurs such that "forbidden lines" can now occur. This is discussed in Sec. 5.

The doublet structure in the microwave spectra is characteristic of the threefold high barrier case, and when the splitting is not too large, the doublets can easily be recognized because the Stark effect is virtually identical for the two lines. Since the δ's and the integrals I are to a good approximation independent of K and σ, the difference between the two corresponding eigenvalues of the degenerate and nondegenerate submatrices for a given J arise only from the terms containing $E_{Kv\sigma}$. Therefore, the splittings of the doublets in the microwave spectrum depend to the first order only on $E_{Kv\sigma}$ but not $\delta_{K'v\sigma}{}^{Kv\sigma}$ and $I_{K'v\sigma}{}^{Kv'\sigma}$ which cause only a shifting in the positions of the lines. The effect of the δ's and I's can be included,[20] but the relations are rather complicated. After the transformation S, the resulting Hamiltonian contains some elements which carry the δ's as coefficients and have the same structure as the ordinary rigid asymmetric rotor matrix elements.[62] As a result the δ's add a correction to the rotational constants which is the same for the degenerate and nondegenerate levels.

Since the energy levels (except $K=0$, $\sigma=0$) are all degenerate for symmetric tops with high barriers, it can be seen that the presence of the asymmetry splits some of these degenerate levels so that the levels with $\sigma=0$ are now nondegenerate. The splitting of the levels by asymmetry can be seen in the following way: to split a pair of degenerate levels of the unperturbed system (the symmetric molecule), say $K=2$, $\sigma=0$, and $K=-2$, $\sigma=0$, it is necessary that the perturbation (the asymmetry) offers matrix elements connecting these two levels directly or through high-order terms. In the present case these two levels do indeed interact with each other through the asymmetry terms as

$$K=2,\ \sigma=0\leftrightarrow K=0,\ \sigma=0\leftrightarrow K=-2,\ \sigma=0.$$

On the other hand, since the asymmetry terms are diagonal in σ, the pairs of levels with quantum number K, $\sigma=1$, and $-K$, $\sigma=-1$ which are degenerate in the symmetric top case, can never connect each other under any high-order interaction. Consequently all the levels with $\sigma=\pm1$ remain doubly degenerate. This is shown in Fig. 4 where the thickness of the levels was drawn to illustrate the degeneracy. Each J, K level has a weight of six from the two K levels and the three internal rotor levels.

At the limit of infinitely high barriers, the δ's and I's approach zero and the energy matrix in Eq. (3-49) reduces to that of a rigid rotor.

5. Splitting of the hindered rotation doublets.—The splittings of doublets associated with the ground torsional level are utilized to determine the barrier height. Hecht and Dennison[20] have given expressions for the differences between the A and E component of a rotational state in the ground torsional level up to $J=3$. With these formulas the barrier can be evaluated from the splittings of the low J rotational lines. For higher J levels the splitting of the A and E levels can be calculated as follows: A transformation S_1S_2' is applied to the Hamiltonian where S_1 corresponds to a rotation of the axes as defined previously and S_2' is the matrix which changes the basis vectors from the symmetric top wave function to the Wang symmetric and antisymmetric combinations. Note that S_2' is different from S_2. Let the transformed Hamiltonian be written as $H_R+H_T+H_{IR}$ where H_R is the rotational part, H_T is the internal rotation part dependent on $E_{Kv\sigma}$, and H_{IR} is the internal rotation part dependent on the integrals which, as pointed out before, have little effect on the splittings of the internal rotation doublets. For slightly asymmetric tops the splittings are caused primarily by

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the difference in the diagonal elements of H_T between the A and E levels provided the asymmetry splitting is not too small.

Approximate formulas for the diagonal elements in the H_T were derived by Lide and Mann[62] for the case of small values of β. These formulas for the splitting of the energy levels follow directly from Eq. (3-55) and are given in Eq. (3-56):

$$\begin{aligned}\Delta E_{JK}&=\Delta_K+(\beta^2/4)[(J+K)(J-K+1)\Delta_{K-1}\\&\quad-2[J(J+1)-K^2]\Delta_K\\&\quad+(J-K)(J+K+1)\Delta_{K+1}],\\\Delta E_{J1}&=\Delta_1+(\beta^2/4)[(J-1)(J+2)(\Delta_2-\Delta_1)],\\&\quad(J+K_{-1}+K_{+1}\text{ even}),\\\Delta E_{J1}&=\Delta_1+(\beta^2/4)[2J(J+1)\Delta_0\\&\quad-(3J^2+3J-2)\Delta_1+(J-1)(J+2)\Delta_2],\\&\quad(J+K_{-1}+K_{+1}\text{ odd}),\\\Delta E_{J0}&=\Delta_0+(\beta^2/2)J(J+1)(\Delta_1-\Delta_0),\end{aligned}\tag{3-56}$$

where

$$\Delta_K=-\tfrac{1}{2}(E_{Kv1}+E_{Kv-1})+E_{Kv0}\approx+\tfrac{3}{2}Fa_1\cos\left(\frac{2\pi}{3}\rho K\right)$$

$$=\Delta_0\cos\left(\frac{2\pi}{3}\rho K\right),\tag{3-57a}$$

$$\Delta_0=+\tfrac{3}{2}Fa_1=+(9/4)F\Delta b.\ddagger\ddagger\ddagger\ddagger\tag{3-57b}$$

In general the off-diagonal elements of H_T should also be considered for the E levels especially when the asymmetry splitting is small. They connect the states corresponding to the symmetric and antisymmetric combination of the symmetric top functions and have the form of

$$(K_+|H|K_-)=\delta_K=+\frac{\alpha}{2}(E_{Kv\sigma}-E_{-Kv\sigma})$$

$$=+\frac{\alpha}{\sqrt{3}}\Delta_0\sin\left(\frac{2\pi}{3}\rho K\right),\tag{3-58}$$

where

$$\alpha=\rho_z/\rho=(1-\beta^2)^{\frac{1}{2}}.$$

Both the quantities Δ_K and δ_K can be approximated by the trigonometric form only when the barrier is relatively high such that $E_{Kv\sigma}$ can be approximated accurately by the Fourier coefficients a_0 and a_1 with the neglect of the higher terms. The term δ_K is equivalent to the linear terms in P_z in the PAM and the term Δ_K is equivalent to the shift in the rotational constants, i.e., $C_{v0}-C_{v1}$.

The asymmetry term is of the form

$$\delta_{Asy}=-\tfrac{1}{4}(A-B)[(J-K)(J-K-1)\times(J+K+1)(J+K+2)]^{\frac{1}{2}}.\tag{3-59}$$

For the $K=1$ levels only, the asymmetry and the off-diagonal elements of H_T compete directly with one another for the shifting of the levels. If the two effects are of the same order of magnitude, then the correction can be determined from the

$$\tfrac{1}{2}(4\delta_K{}^2+\delta_{Asy}{}'^2)^{\frac{1}{2}}.\tag{3-60}$$

Here $\delta_{Asy}{}'$ is the asymmetry splitting and not the asymmetry term (note that for $K=1$, they are the same). If $\delta_K\gg\delta_{Asy}{}'$, the suitable zeroth-order basis functions are no longer the Wang functions but rather the symmetric rotor functions. After the transformation S_1, the energy matrix can then be diagonalized exactly or by perturbation methods. If, on the other hand, $\delta_{Asy}{}'>\delta_K$, then the splitting due to the off-diagonal elements of H_T must be calculated by the proper asymmetric rotor wave functions, i.e., the effects of β^2 and higher-order terms should be considered. Lide and Mann[62] have derived expressions to the order β^2 for the frequencies of the parallel transition, $J+1, K\leftarrow J, K$.

6. General case.—The most general type of molecules, where the internal rotor is arbitrarily located with respect to the principal axes, has been considered by Pitzer and Gwinn,[84] Hecht and Dennison,[20] and Burkhard.[7] The method follows in an analogous manner, only with added complications. As an aid in the computation it is usually easier to determine the molecular parameters such as ϱ and r by the PAM and then convert them to the IAM.

7. Intermediate barrier case.—If the barrier hindering internal rotation becomes too low for the high barrier approximation to be valid, the matrix elements off-diagonal in v would have appreciable effect on the energy levels. The whole matrix can then be diagonalized either exactly or approximately by using modified perturbation procedure.

Methyl alcohol, methyl amine, and methyl mercaptan are examples of molecules with intermediate barriers, i.e., low s values. Considerable work has been done on these molecules and this is discussed in Sec. 8. The low s values in these molecules are caused in part by the small reduced moment of the methyl group. With the light asymmetric frames, these molecules have only a slight symmetry. All the off-diagonal matrix elements due to asymmetry and internal rotation are small and their effect can be calculated by perturbation theory. For the main Q branch series ($\Delta J=0$, $\Delta K=\pm1$) reported, the transition positions are determined essentially by the limiting symmetric top rotational transition plus the internal rotational transition. The off-diagonal elements contribute small terms which can be expanded in a power series of $J(J+1)$. The coefficients of these power series are the perturbation correction terms including centrifugal distortion. Usually some parallel transitions are needed in addition to aid in the structural determination.

Should the asymmetry be large, the solution of the low reduced barrier problem is quite difficult. With the

‡‡‡‡ Here, Δ_0 is the negative of Δ_0 in reference 20 because we have taken the A level minus the E level. Here Δb is the difference between the values of b [see Eq. (3-4)] for the A and E sublevels of a torsional state.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

matrix elements given in Eq. (3-49) a diagonalization of the low J energy matrices could be made. The $(v|v')$ connections probably could be treated to sufficient accuracy by perturbation calculations. Evaluation of the torsional functions needed for calculating the matrix elements is discussed in Appendix 2.

4. LOW BARRIER APPROXIMATIONS

The barriers of most molecules determined from the microwave spectra are in the category of a "high barrier," i.e., of the order of 0.7–5.0 kcal. Here the "high barrier approximation" (Sec. 3) can be used, in which both a rotational and a torsional equation are solved, and any interaction removed by a transformation. In the low barrier approximation the free internal rotational problem is solved exactly and then the barrier is added as a perturbation. So far two molecules have been treated by this method; they are nitromethane (CH_3NO_2)[106,107] and methyl difluoroboron (CH_3BF_2).[74,75]

The possession of a sixfold symmetry in these two molecules is believed to be the cause for the low value of the barrier. Consider the case of CH_3NO_2. The interaction of a single oxygen with the methyl group gives rise to a barrier to internal rotation in the form

$$\tfrac{1}{2}V_3(1-\cos 3\alpha)+\tfrac{1}{2}V_6(1-\cos 6\alpha)+\tfrac{1}{2}V_9(1-\cos 9\alpha)+\cdots.$$

The second oxygen contributes another potential barrier which is 180° out of phase with the one from the first oxygen. The potential due to both oxygen atoms is then

$$V_6(1-\cos 6\alpha)+V_{12}(1-\cos 12\alpha)+\cdots.$$

The present discussion is therefore confined primarily to molecules with sixfold symmetry. The treatment given can, in principle, be extended to the more general case though the actual analysis might become quite complicated.

I. Free Rotation

A. Symmetric Molecules

For symmetric molecules the difference between the solution by the principal axes method and the internal axis method is not as distinct as in the high barrier problems because the torsional equation with its different boundary conditions is now eliminated.

In the PAM, the Hamiltonian is[121]

$$H=A_x(P_x^2+P_y^2)+C_zP_z^2+Fp^2-2C_zpP_z, \quad (4\text{-}1)$$

where

$$A_x=\hbar^2/2I_x=\hbar^2/2I_y=A, \quad (4\text{-}2a)$$

$$C_z=\hbar^2/[2(I_z-I_\alpha)], \quad (4\text{-}2b)$$

$$F=\hbar^2/2rI_\alpha=\hbar^2I_z/[2I_\alpha(I_z-I_\alpha)]. \quad (4\text{-}2c)$$

This equation can be rearranged to Eq. (4-3),

$$H=A(P_x^2+P_y^2)+CP_z^2+F(p-(I_\alpha/I_z)P_z)^2. \quad (4\text{-}3)$$

But this is just Eq. (2-9) in the IAM.[48] The eigenfunctions of these two equations are

$$S_{JKM}(\theta,\varphi)e^{iK\chi}e^{im\alpha}, \quad (4\text{-}4)$$

where m is an integer. The eigenvalues corresponding to Eq. (4-1) and Eq. (4-3) are then, respectively,

$$E=AJ(J+1)+(C_z-A)K^2+Fm^2-2C_zKm, \quad (4\text{-}5)$$

$$E=AJ(J+1)+(C-A)K^2+F[m-(I_\alpha/I_z)K]^2. \quad (4\text{-}6)$$

However, if the IAM Hamiltonian Eq. (2-20) is used in which χ' and α' are the variables, then the eigenfunctions are

$$S_{JKM}(\theta,\varphi)e^{iK\chi'}e^{im'\alpha'}. \quad (4\text{-}7)$$

The choice of m' is governed by the boundary conditions, i.e., the wave function must be invariant under the transformation

$$\chi_1\rightarrow\chi_1+2\pi n_1 \quad \chi_2\rightarrow\chi_2+2\pi n_2. \quad (4\text{-}8)$$

With Eq. (2-15) and following the same method as used in Eq. (3-20) we obtain the result

$$m'=l-(I_\alpha/I_z)K, \quad (4\text{-}9)$$

where l is an integer. Consequently the eigenvalues given in Eq. (4-10) are obtained:

$$E=AJ(J+1)+(C-A)K^2+F[l-I_\alpha/I_z)K]^2. \quad (4\text{-}10)$$

Clearly, if we identify l with m, Eq. (4-10) is identical to Eq. (4-6).

The selection rules for the microwave spectra can be stated as $\Delta J=\pm1$, $\Delta K=0$, $\Delta m=0$ (see Sec. 6) (or $\Delta l=0$). The frequencies of the rotational transitions are

$$\nu_{J+1\leftarrow J}=2A(J+1), \quad (4\text{-}11)$$

which are exactly the same as those for a rigid symmetrical rotor. Therefore, the effect of completely free rotation in symmetric tops cannot be detected from the microwave spectra.

B. Asymmetric Molecules (CH_3NO_2 *type*)

If the methyl group of CH_3NO_2 were allowed to execute free rotation (zero hindering barrier), the microwave spectrum would be considerably different from a rigid molecule. The Hamiltonian may be split into that of a symmetric internal rotor plus the asymmetry term, i.e.,

$$H=H_0+H_1,$$

where

$$H_0=\tfrac{1}{2}(A+B)(P_x^2+P_y^2)+C_zP_z^2+Fp^2-2C_zpP_z, \quad (4\text{-}12a)$$

$$H_1=\tfrac{1}{2}(A-B)(P_x^2-P_y^2). \quad (4\text{-}12b)$$

By using the basis functions Eq. (4-4) which diagonal-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ize H_0, we obtain the matrix elements

$$(JKm|H|JKm)=\tfrac{1}{2}(A+B)J(J+1)+[C_z-\tfrac{1}{2}(A+B)]K^2+Fm^2-2C_zKm,$$

$$(JKm|H|J,K\pm2,m)=-\tfrac{1}{4}(A-B)[J(J+1)-K(K\pm1)]^{\frac{1}{2}}\cdot\times[J(J+1)-(K\pm1)(K\pm2)]^{\frac{1}{2}}. \quad (4\text{-}13)$$

The Hamiltonian is diagonal in J, m, and M and the energy matrix consists of submatrices of the order $2J+1$ for a given set of J, m, and M. As different values of K are connected only in steps of two by the off-diagonal elements, each of the submatrices can be factored into even and odd K blocks. When m is equal to zero, the secular equation degenerates into one identical to that of a rigid asymmetric rotor with the exception that C_z is the rotational constant of the framework alone rather than the entire molecule. For $m\neq0$, the Wang transformation does not lead to further factoring of the secular equation because of the presence of the elements linear in K. As examples, the secular determinant with odd values of K for $J=1$ and $J=2$ are given below. The terms independent of K in the diagonal elements have been omitted since they can be regarded as additive constants for a given J and m.

$$J=1\begin{vmatrix}[C_z-\frac{1}{2}(A+B)]-2mC_z-\lambda & -\frac{1}{2}(A-B)\\ -\frac{1}{2}(A-B) & [C_z-\frac{1}{2}(A+B)]+2mC_z-\lambda\end{vmatrix}=0 \quad (4\text{-}14)$$

$$J=2\begin{vmatrix}[C_z-\frac{1}{2}(A+B)]-2mC_z-\lambda & -\frac{3}{2}(A-B)\\ -\frac{3}{2}(A-B) & [C_z-\frac{1}{2}(A+B)]+2mC_z-\lambda\end{vmatrix}=0 \quad (4\text{-}15)$$

For each m there exists an identical secular equation corresponding to $-m$ and hence the energy levels (with $m\neq0$) are all doubly degenerate. The selection rules (see Sec. 6) for dipole radiation are identical to those of rigid asymmetric tops with the additional restriction of $\Delta m=0$. If the dipole moment is along the z axis, the parity of K cannot change.

From the secular equations (4-14) and (4-15) the frequencies of the $J=2\leftarrow1$ odd K, parallel transitions ($\Delta K=0$) are given by

$$\nu_{2\leftarrow1}{}^{\text{odd }K}=2(A+B)+\lambda_2-\lambda_1=2(A+B)\pm\{[4mC_z{}^2+(9/4)(A-B)^2]^{\frac{1}{2}}-[4m^2C_z{}^2+\tfrac{1}{4}(A-B)^2]^{\frac{1}{2}}\}. \quad (4\text{-}16)$$

For each value of m, two lines are predicted which are symmetrically spaced with respect to the midfrequency of $2(A+B)$. As m increases, the separation between the pair becomes smaller and finally the transitions converge to the band head of $\nu=2(A+B)$. This effect has been observed on CH_3NO_2 by Tannenbaum, Myers, and Gwinn[106,107] and on CH_3BF_2 by Naylor and Wilson.[74,75] The intensities of the higher members would tend to decrease on account of the unfavorable Boltzmann factors.

The other $J=2\leftarrow1$ transition which is even in K, can be treated in a similar manner. As Naylor and Wilson[74,75] have pointed out, the $J=1$, $K=0$ eigenvalue is zero and the $J=2$, $K=0$ eigenvalue is positive, decreasing with increasing m. This group of lines therefore converge toward $2(A+B)$ from the high-frequency side as m increases. For large values of m the energy matrix Eq. (4-13) may be solved by second-order perturbation theory which leads to

$$E=\tfrac{1}{2}(A+B)J(J+1)+[C_z-\tfrac{1}{2}(A+B)]K^2+Fm^2-2C_zKm+\frac{(A-B)^2}{64\{[C_z-\frac{1}{2}(A+B)](K-1)-C_zm\}}\times[J^2-(K-1)^2][(J+1)^2-(K-1)^2]-\frac{(A-B)^2}{64\{[C_z-\frac{1}{2}(A+B)](K+1)+C_zm\}}\times[J^2-(K+1)^2][(J+1)^2-(K+1)^2]+\cdots. \quad (4\text{-}17)$$

The transitions of the type $\Delta J=\pm1$, $\Delta K=0$,§§§§ $\Delta m=0$ again give rise to a band-like structure for each given J.

II. A Low Sixfold Barrier

The sixfold potential barrier introduces to the Hamiltonian an additional term of the form

$$V(\alpha)=(V_6/2)(1-\cos6\alpha)=(V_6/4)(2-e^{i6\alpha}-e^{-i6\alpha}). \quad (4\text{-}18)$$

The first term $\frac{1}{2}V_6$ merely represents a common additive constant and can be safely dropped. The energy matrix analogous to Eq. (4-13) is

$$(JKm|H|JKm)=\tfrac{1}{2}(A+B)J(J+1)+[C_z-\tfrac{1}{2}(A+B)]K^2+Fm^2-2mC_zK$$

$$(JKm|H|J,K\pm2,m)=-\tfrac{1}{4}(A-B)\{[J(J+1)-K(K\pm1)][J(J+1)-(K\pm1)(K\pm2)]\}^{\frac{1}{2}} \quad (4\text{-}19)$$

$$(JKm|H|JK,m\pm6)=-\tfrac{1}{4}V_6.$$

When V_6 is small, the nondiagonality in m may be re-

§§§§ In the present case K is nearly a good quantum number.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

moved by a Van Vleck transformation.[34] To the second-order approximation the matrix elements reduce to those given in Eq. (4-13) with the additional diagonal term

$$\frac{V_6^2}{192[C_zK-F(m+3)]}-\frac{V_6^2}{192[C_zK-F(m-3)]}=\frac{FV_6^2}{32[(C_zK-Fm)^2-9F^2]}. \quad (4\text{-}20)$$

The submatrices for m and $-m$ are still identical and the energy levels remain doubly degenerate. Calculations show that the two correction terms from the Van Vleck transformation in Eq. (4-20) have very little effect on the frequency provided $\frac{1}{4}V_6 \ll F$. The spectrum is therefore almost identical to that for free rotation. The validity of Eq. (4-20) depends, of course, on the relative magnitude of V_6 and F. When the potential barrier becomes larger it is necessary to consider the third- and fourth-order terms from the Van Vleck transformation, but it has been indicated[74] that even when the effect of the higher terms may be quite appreciable as far as the positions of the energy levels are concerned, the effect on the frequency may be negligible.

The foregoing treatment is not directly applicable to the $|m|=3$ levels because a near degeneracy exists and it becomes necessary to consider the $m=-3$ and $m=3$ block as a single secular equation. The matrix elements connecting 3 with 9 and -3 with -9 can, however, still be treated by the Van Vleck procedure. An example is furnished by the block corresponding to $J=1$, K odd:

mK	$(-3,-1)$	$(-3,1)$	$(3,-1)$	$(3,1)$
$(-3,-1)$	a	b	$-\frac{1}{4}V_6$	0
$(-3,+1)$	b	a'	0	$-\frac{1}{4}V_6$
$(3,-1)$	$-\frac{1}{4}V_6$	0	a'	b
$(3,1)$	0	$-\frac{1}{4}V_6$	b	a

(4-21)

where

$$a=\tfrac{1}{2}(A+B)+C_z+9F-6C_z-\frac{V_6^2}{192(6F-C)},$$

$$a'=\tfrac{1}{2}(A+B)+C_z+9F+6C_z+\frac{V_6^2}{192(6F+C)},$$

$$b=-\tfrac{1}{2}(A-B).$$

The symmetry about the antidiagonal allows this matrix to be factored through a transformation which is equivalent to choosing wave functions of the type

$$\frac{1}{\sqrt{2}}[\psi(K, m=3)\pm\psi(-K, m=-3)]. \quad (4\text{-}22)$$

The two resulting matrices are

$$\begin{bmatrix} a' & b+\frac{1}{4}V_6 \\ b+\frac{1}{4}V_6 & a \end{bmatrix}, \quad (4\text{-}23a)$$

and

$$\begin{bmatrix} a' & b-\frac{1}{4}V_6 \\ b-\frac{1}{4}V_6 & a \end{bmatrix}. \quad (4\text{-}23b)$$

The double degeneracy discussed in the previous paragraph and in the free-rotor case is now split by the barrier when $|m|=3$. In fact the energy levels corresponding to m equal to whole multiple of three are all nondegenerate (see Fig. 2). The higher the multiple of three, the higher the order of perturbation required to demonstrate the splitting. The method for calculating these splittings is very similar to that used for the λ doubling in diatomic molecules.

There are now four lines for the $J=2\leftarrow 1$ transition with odd K and $|m|=3$. These four lines appear as two pairs, both symmetrically spaced about the band head $\nu=2(A+B)$ and the splittings of these two pairs of lines are extremely sensitive to the barrier height. In CH_3BF_2 the splitting of one of these pairs, which would be practically coincident at the limit of zero barrier, amounts to about 4000 Mc, for a barrier of 14 cal/mole. These splittings are what make it possible to determine the barrier height with a high degree of accuracy from the microwave spectra.

The selection rules are given approximately by

$$\Delta J=0,\pm 1;\quad \Delta K=0;\quad \Delta m=0.$$

Exact selection rules may be obtained by the group theoretical treatment (Sec. 6) or by an explicit evaluation of the transition moments.

In principle three sets of lines should be observed. The first set, which has the structure of the ordinary rigid asymmetric top spectrum, corresponds to $m=0$. Analysis of these lines yields the two principal moments of inertia perpendicular to the axis connecting the internally rotating groups (the $C-N$ or $C-B$ bond)‖ ‖ ‖ ‖ and also the moment of inertia of the framework about this axis. The second set consists of all the lines with $m\neq 0$ and $m\neq 3$. A band structure is observed if a sufficient number of high m transitions is detected. The $|m|=3$ lines constitute the third set and the splittings of these lines are used to determine the barrier height accurately.

III. A Low Threefold Barrier

The problem of a low threefold potential barrier can be handled in essentially the same fashion. The paper by Wilson, Lin, and Lide[121] gives a treatment for a general N-fold barrier. Here, however, there are no

‖ ‖ ‖ ‖ Nuclear spin symmetry (see Sec. 6) in CH_3NO_2 allows only those energy levels with $K-m$ even so that the second set is also needed to determine the moments of inertia.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

degenerate levels like the $|m|=3$ for the sixfold barrier which are connected by matrix elements of the barrier. Therefore, the barrier height cannot be as accurately determined. Recently $CH_3C\equiv CCH_2Cl$ has been studied[53b] and an estimate of the barrier height has been given.

5. CALCULATIONS OF BARRIER HEIGHTS

After the rather lengthy discussions of the high barrier approximation and the low barrier approximation for the IAM and PAM, the casual reader may be a little perplexed as to when the approximations are valid and which representation to use. Consequently, it seems desirable to give a few suggestions in regard to the analyses of microwave spectra, characteristics of the spectra, and methods of calculation.

I. Analyses of Microwave Spectra

As pointed out previously, the effects of rigid internal rotation are not observed in a symmetric top molecule. As a result, all the applications of internal rotational theory have been done on asymmetric molecules. The methods for determining the barrier heights for the symmetric top molecules from the microwave spectra are discussed in Sec. 7.

For convenience the effect of internal rotation in an asymmetric molecule can be subdivided into the following groups according to the magnitude of the parameter s as defined in Eqs. (3-4):

(*1*) *The pseudo-rigid rotor case* ($s>30$).—With a relatively high barrier and large asymmetry splittings, i.e., the asymmetry splittings are larger than the internal rotation splittings, both members of a transition follow a rigid-rotor spectrum. This is especially true of the low K energy levels with the possible exception of the $K=1$ levels.

The splittings due to the internal torsion may be ascribed to the Δ_K term [Eqs. (3-57)] in the IAM or the ΔW term [cf. Eq. (3-38)] in the PAM. Acetyl fluoride[80] is an example of this class of molecules.

For the ground torsional state, the frequencies of the A transitions are generally somewhat higher than those of the corresponding lines of the rigid molecule while the E transitions usually have lower frequencies. The shift of the A line from the "unperturbed position" is approximately twice that of the E line. This follows from the fact that according to Eqs. (3-57) and (3-28), $\frac{1}{2}(E_{Kv1}+E_{Kv-1})$ is approximately equal to $-\frac{1}{2}E_{Kv0}$ or from Eq. (3-33) and Table II, $w_{01}^{(2)}$ is very close to $-\frac{1}{2}w_{00}^{(2)}$. Many exceptions to this rule can occur, especially for the $K=1$ energy levels, but generally it is a useful first approximation.

(*2*) *A departure of the E levels from a pseudo-rigid rotor pattern* ($15<s<30$).—The δ_K term in the IAM or the $w_{01}^{(1)}$ term in the PAM causes the E energy levels to depart from a rigid-rotor pattern and for a given K the two $\Delta K=0$ transitions tend toward one another so that the spectrum becomes similar to that of a slightly asymmetric top. In other words, the internal rotation cancels out part of the asymmetry. This δ_K term is especially important for the $K=1$ energy levels because both the asymmetry and this "nonrigid-rotor term"

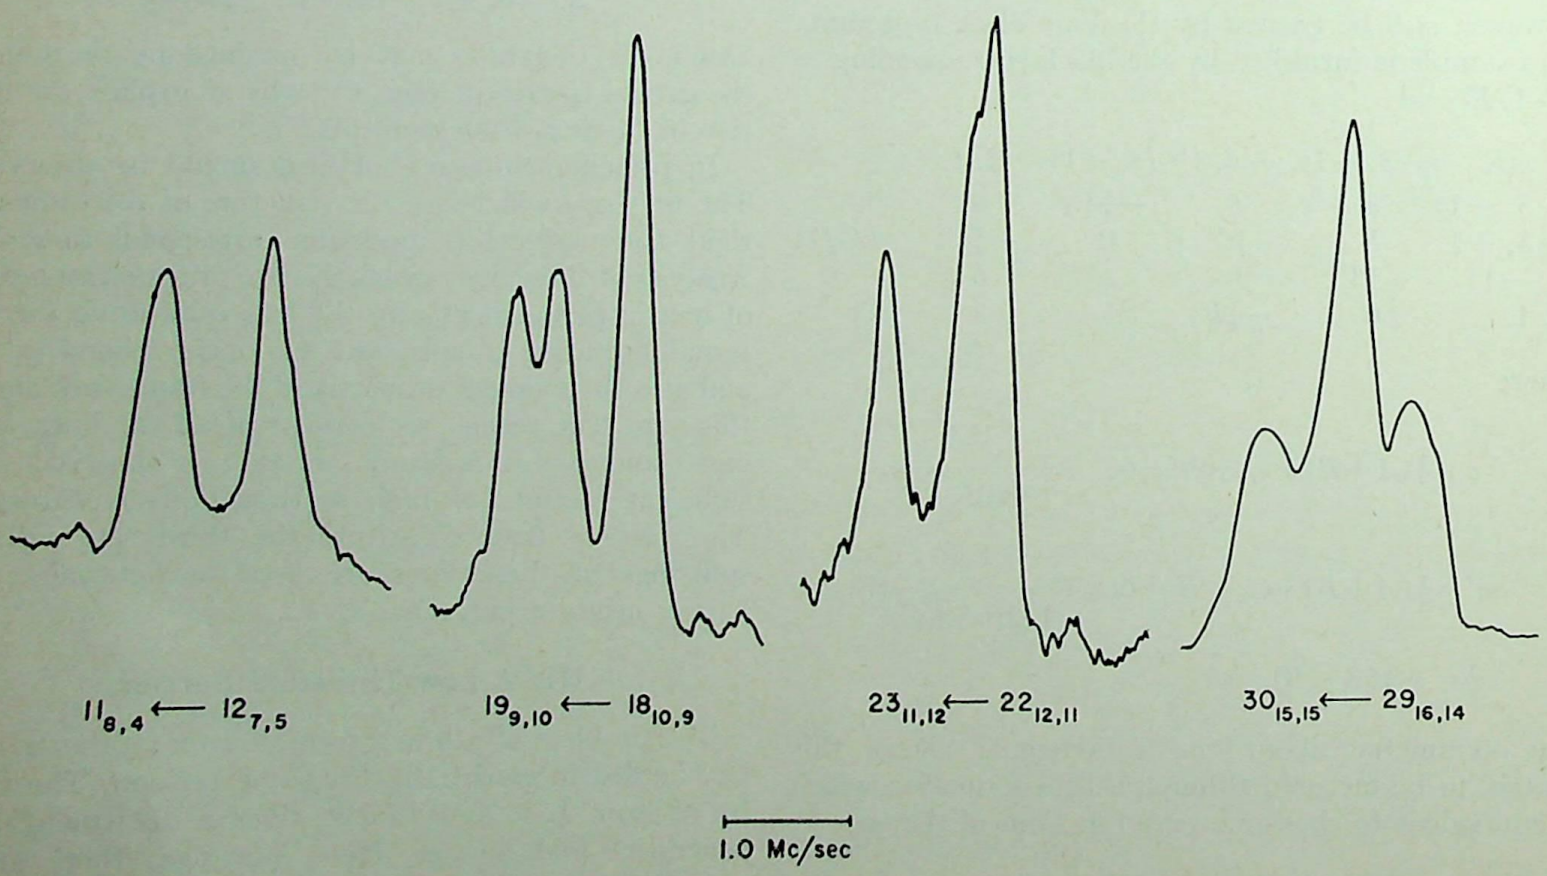

FIG. 5. High K transitions in propylene oxide.[27] The two E lines are superimposed on the left of the first transition but split in the second transition as K increases. In the third transition the E line is now under the A line and finally comes out the other side on the last transition.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

connect the same pair of levels. If either the asymmetry term or the internal rotation term dominates to a large degree, the other can be treated as a perturbation.[62] If the two terms are of the same order of magnitude, then a 2×2 matrix must be solved (cf. Sec. V).

(3) *High K energy levels.*—The high K energy levels of an asymmetric rotor are nearly degenerate even for very large values of asymmetry, so the internal rotational splittings often dominate the asymmetry splittings. These high J, high K energy levels are very similar to symmetric rotor levels except for a shift due to the asymmetry. For the parallel type transitions ($\Delta K=0$) very little splittings are observed, but for the perpendicular transitions ($\Delta K=\pm1$) a triplet is observed consisting of an A symmetry line and two E symmetry lines. This is explained in Sec. 6 II. B. Propylene oxide[27] is an example of this group and some of these triplets are shown in Fig. 5.

(4) *Intermediate barrier heights* ($s<15$).—When the internal rotational splittings are of the order of the spacings between different rotational levels, then the various approximations used in the high barrier case are not generally valid. This is true especially for the perpendicular transitions. Consequently, a more detailed calculation is needed. The IAM is usually recommended for the intermediate barrier problem, especially for the slightly asymmetric molecules, e.g., methyl alcohol. As a guide to the first analysis, the low J parallel transitions should be used to obtain the approximate barrier height and molecular structure since these lines are relatively barrier insensitive. A more detailed analysis of the perpendicular transitions is then made to determine the barrier height more accurately. For molecules with large asymmetry (such as acetic acid[105]) many times the PAM is more convenient.

(5) *Low barrier heights* ($s<2$).—For barrier heights in this region the low barrier approximation given in Sec. 4 is recommended. A considerable number of lines will be observed with all the possible m values. Naturally the Boltzmann factor eventually decreases the intensity of the high m lines.

Generally, the $m=0$ lines should be analyzed first, followed by the low m (except $|m|=3$) transitions which are relatively barrier insensitive. Then an accurate barrier height can be obtained from the $|m|=3$ levels which are widely split by the sixfold potential energy term.

Finally, in the analysis of the spectra, regardless of the s values, the choice of the axis of quantization is gauged by the axis of internal rotation in both the IAM and PAM. This follows directly for the IAM. In the PAM the principal axes closest to the top axes are used as the z axes even if this does not conform to the best choice for the solution of asymmetric rotor energy levels.[41]

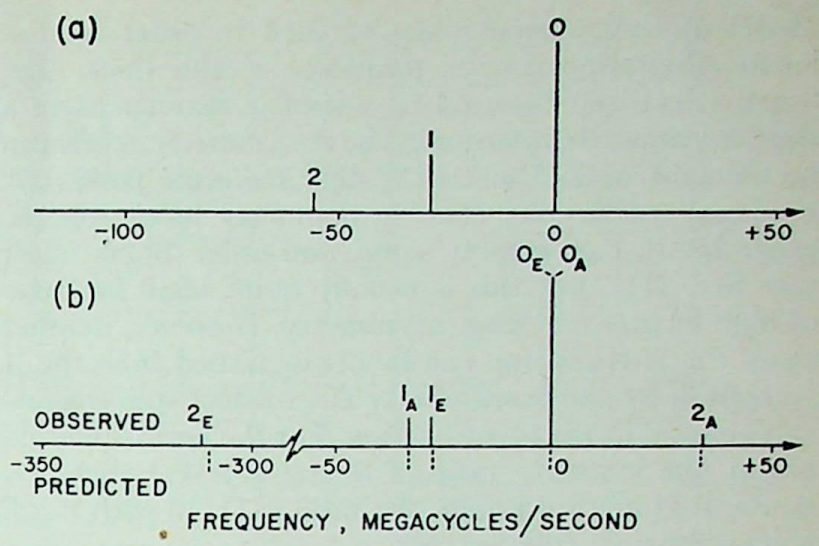

FIG. 6. A rotational line in the ground state and excited vibrational (or torsional) states. (a) The rotational lines of the ground state and first two excited vibrational levels (or torsional levels without internal rotational splitting). (b) The same pattern including internal rotational splitting into the A and E lines. The observed spectrum is from propylene oxide.[27]

II. General Characteristic of the Spectra

While the most intense part of the spectrum for molecules with a relatively high barrier arises from the transitions in the ground torsional state, the rotational transitions in the excited torsional states are usually observable. For example, at room temperature the intensities of the spectral lines from the first excited state could be reduced by a factor of two or three and those from the second excited states by a factor of about ten. These weaker lines (known as satellites) are shifted from the main line associated with the ground torsional state because of the influence of the vibration of the molecule. This total effect is taken into account by using effective rotational constants B_i which are related to the actual rotational constants B_e as $B_i=B_e-\Sigma_i\times(v_i+\frac{1}{2})\alpha_i$. The splittings between the A and E satellite lines in the "heavy" molecules are, however, rather insensitive to the effect of molecular vibrations and, to a first approximation, are caused by the internal rotation only. The general formulas for the A and E splittings developed in Sec. 3 are applicable to the rotational lines in the excited torsional states provided that such torsional levels are far below the top of the potential barrier. As the internal rotation splittings become magnified in the excited torsional states, the potential barrier many times can be determined from the splittings of the satellites.[22] In propylene oxide[27,101] the same barrier can account for the splittings of the rotational lines in the three lowest torsional levels (see Fig. 6). In the lighter molecules, such as methyl alcohol and methyl silane,[42] the splittings of the satellite rotational lines cannot be completely ascribed to the internal rotation. This is because the effects of molecular vibrations contribute appreciably to the splittings as well as the frequency shifts of the rotational lines in the excited states.

In the identification of microwave transitions, a rigid

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

model of the molecule can be used in order to first locate the approximate positions of the lines. The Stark effect can be used in a similar manner as in a rigid asymmetric molecule. The A symmetry levels can be thought of as those of a rigid molecule possessing torsional oscillations. The E symmetry levels, on the other hand, can exhibit some first-order Stark effect (see Sec. III), but this is usually quite small for cases of high barrier and large asymmetry. However, in other cases the E transition can be distinguished from the A transition by the Stark effect. The nuclear spin weights can also aid in the identification. For the normal methyl group, the intensity ratio of A and E is 1:1; but in a deuterated methyl group, the ratio is 11:16 with the E level stronger[38] (see Sec. 6).

With the identification of the various transitions, approximate unperturbed rotational constants can be determined by using either the average position of the A and E doublet or else two-thirds the doublet separation from the A line. The latter method is a better approximation except for the $K=1$ levels. With the approximate rotational constants one can determine the structure of the molecule which along with the A-E splittings may be used to obtain the barrier height. Successive iterations lead to more accurate results.

III. Stark Effect

For the case of free rotation, the lines with $m=0$ show a second-order Stark effect (first order if accidental degeneracy exists) which is a characteristic of a rigid-rotor spectrum. When m is not equal to zero the situation is different. As stated before, the Wang combinations of the K and $-K$ symmetric top functions are no longer the proper zeroth-order wave functions because of the presence of the linear K terms in the secular equation. For example, an eigenfunction for $J=1$ and odd values of K may be written as

$$\Psi=a\psi(K=1)+b\psi(K=-1), \tag{5-1}$$

where a and b are not identical. The expectation values of the direction cosines between the electric field and the body-fixed z axis is then

$$\int\Psi^*\cos\theta\Psi d\tau=\frac{(a^2-b^2)KM}{J(J+1)}. \tag{5-2}$$

This leads us to the conclusion that, in general, a first-order Stark effect is observed provided m, K, and M are all different from zero. For example, with $J=1\leftarrow 0$ only $\Delta K=0$ and $\Delta M=0$ are allowed and the transitions have a second-order Stark lobe while the Stark effect of the $J=2\leftarrow 1$ transitions (with odd K) is first order for $M=\pm 1$ and second order for $M=0$.

When the barrier is low[75,107] the Stark patterns of the lines with $|m|\neq 3$ are practically identical to those for free rotation as the Van Vleck transformation offers only minor modifications to the wave functions. However, for the case of $|m|=3$, the transformation [see Eq. (4-22)] eliminates the diagonal elements of $\cos\theta$. The resulting off-diagonal elements then give rise to a second-order Stark effect with a large Stark coefficient analogous to the case of near degeneracy in rigid asymmetric tops. This serves as a means for identifying the $|m|=3$ lines.

When the barrier becomes higher, the asymmetry has a larger influence. The coefficients a and b in Eq. (5-1) depend on δ_K and δ_{Asy}' (defined in Sec. 3) as

$$a^2-b^2=\pm 2\delta_K(4\delta_K^2+\delta_{\mathrm{Asy}}^2)^{-\frac{1}{2}}. \tag{5-3}$$

Since δ_K is very barrier sensitive, the first-order Stark effect rapidly vanishes as the barrier height is increased.

IV. High Barrier Case

In the symmetric top case, the energy associated with the internal rotation for the IAM is expanded in a Fourier series [Eq. (3-27)] while for the PAM it is expanded in a power series [Eq. (3-13)] as

$$E_{Kv\sigma}=F\left[a_0+a_1\cos\frac{2\pi}{3}(\rho K-\sigma)+a_2\cos\frac{4\pi}{3}(\rho K-\sigma)+\cdots\right], \tag{5-4}$$

$$E_{Kv\sigma}=F[w_{v\sigma}{}^{(0)}+w_{v\sigma}{}^{(1)}\rho K+w_{v\sigma}{}^{(2)}(\rho K)^2+\cdots]. \tag{5-5}$$

In Fig. 7, the various Fourier coefficients are plotted from $s=10$ to $s=100$ on a semilogarithmic scale, and in Fig. 8, the coefficients of the power series in Eq. (5-5) are given. From Eqs. (5-4) and (5-5) the connecting relations between these two types of coefficients can easily be established. They are given in Table III.

TABLE III. The relations between the Fourier coefficients and the power series coefficients [see Eqs. (5-4) and (5-5)].

Factor $N^2/4$	a_0	a_1	a_2	a_3	a_4	a_5
$b(\pi)$	1	1	1	1	1	1
$b(2\pi)$	1	−1	1	−1	1	−1
$b(3\pi)$	1	$-\frac{1}{2}$	$-\frac{1}{2}$	1	$-\frac{1}{2}$	$-\frac{1}{2}$
$b(4\pi)$	1	0	−1	0	1	0
$b(6\pi)$	1	$\frac{1}{2}$	$-\frac{1}{2}$	−1	$-\frac{1}{2}$	$\frac{1}{2}$
$(N^2/4)b(\pi x)$	$a_0+a_1\cos(2\pi/x)+a_2\cos(4\pi/x)+a_3\cos(6\pi/x)+\cdots$					
Threefold case ($N=3$)						
$\frac{3}{2}[b(\pi)-b(3\pi)]$		1	1	0	1	1
$(9/8)[b(\pi)-b(2\pi)]$		1	0	1	0	1
$-2\sqrt{3}p_{vv}/\pi=\sqrt{3}w_{v1}{}^{(1)}/\pi$		1	−2	0	4	−5
$-9w_{v0}{}^{(2)}/2\pi^2$		1	4	9	16	25
$+9w_{v1}{}^{(2)}/\pi^2$		1	4	−18	16	25
$-3\Delta w_v{}^{(2)}/\pi^2$		1	4	0	16	25
$(w_{v1}{}^{(2)}+\frac{1}{2}w_{v0}{}^{(2)})/(3\pi^2)$		0	0	−1	0	0
$-27\sqrt{3}w_{v1}{}^{(3)}/2\pi^3$		1	−8	0	64	−125
$+243w_{v0}{}^{(4)}/2\pi^4$		1	16	81	256	625
$-243w_{v1}{}^{(4)}/\pi^4$		1	16	−162	256	625

e.g., $(N^2/4)b(3\pi)=a_0-\frac{1}{2}a_1-\frac{1}{2}a_2+a_3-\frac{1}{2}a_4-\frac{1}{2}a_5$ and $-[9w_{v0}{}^{(2)}/2\pi^2]=a_1+4a_2+9a_3+16a_4+25a_5+\cdots$.

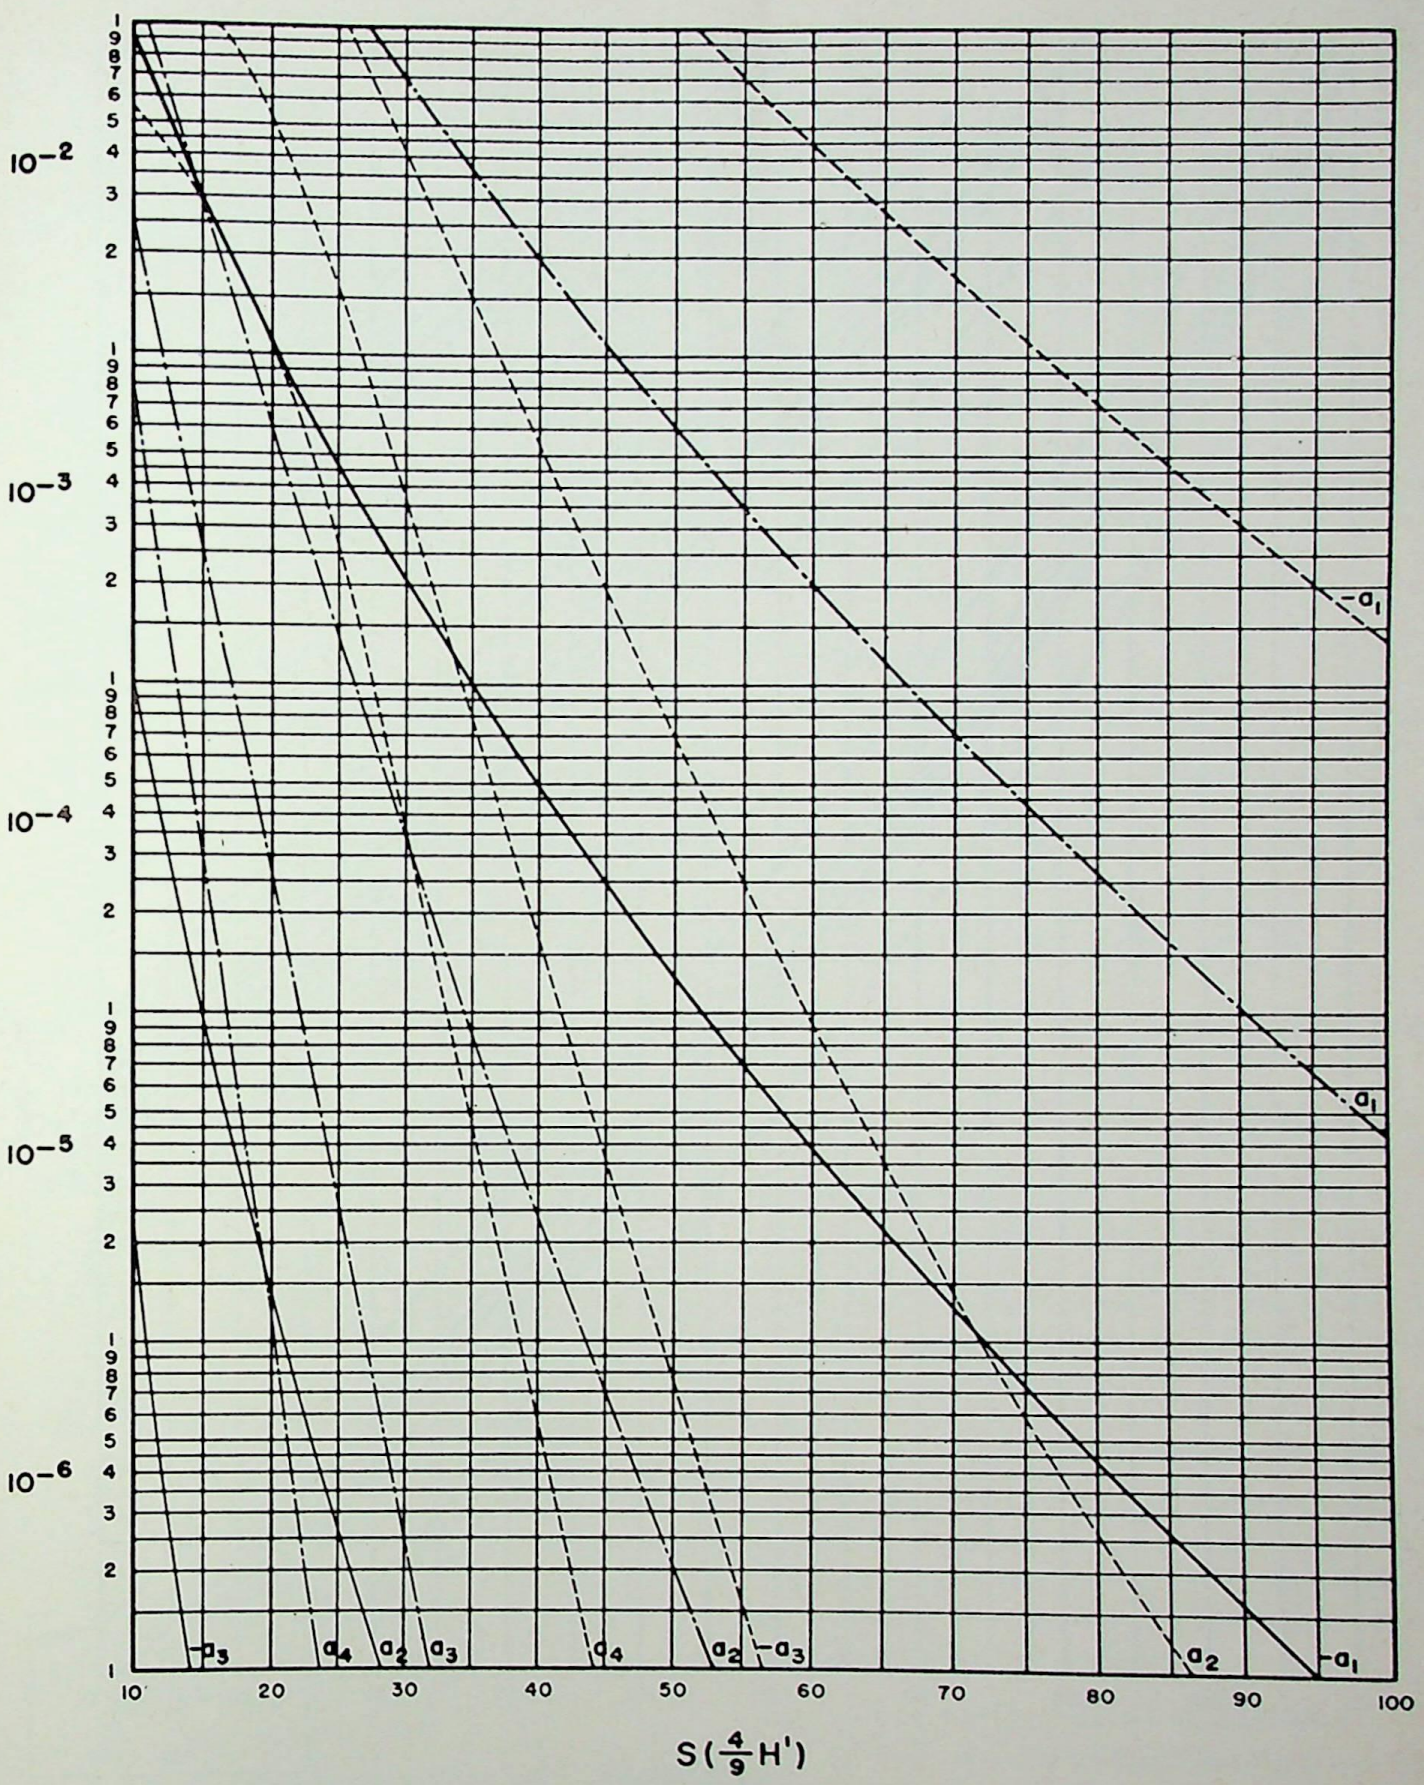

FIG. 7. The Fourier coefficients as a function of the reduced barrier height s for the various torsional levels [see Eq. (5–4)]. ——, $v=0$; —·—, $v=1$; – – – –, $v=2$.

Although these formulas were derived for the symmetric top molecules, they are also applicable to the asymmetric molecules with the necessary modification of F and ρ.

Each of the coefficients (except a_0) are very barrier sensitive, as shown in Figs. 7 and 8. They approximate a functional form of the type $As^{-B}\exp(-C\sqrt{s})$.[20,99] Empirical formulas for the coefficients in Eqs. (5-4) and (5-5) determined by curve fitting are displayed in Table IV. For the high barriers only the Fourier coefficient a_1 is needed from which all the perturbation coefficients of the PAM can be calculated. The domi-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

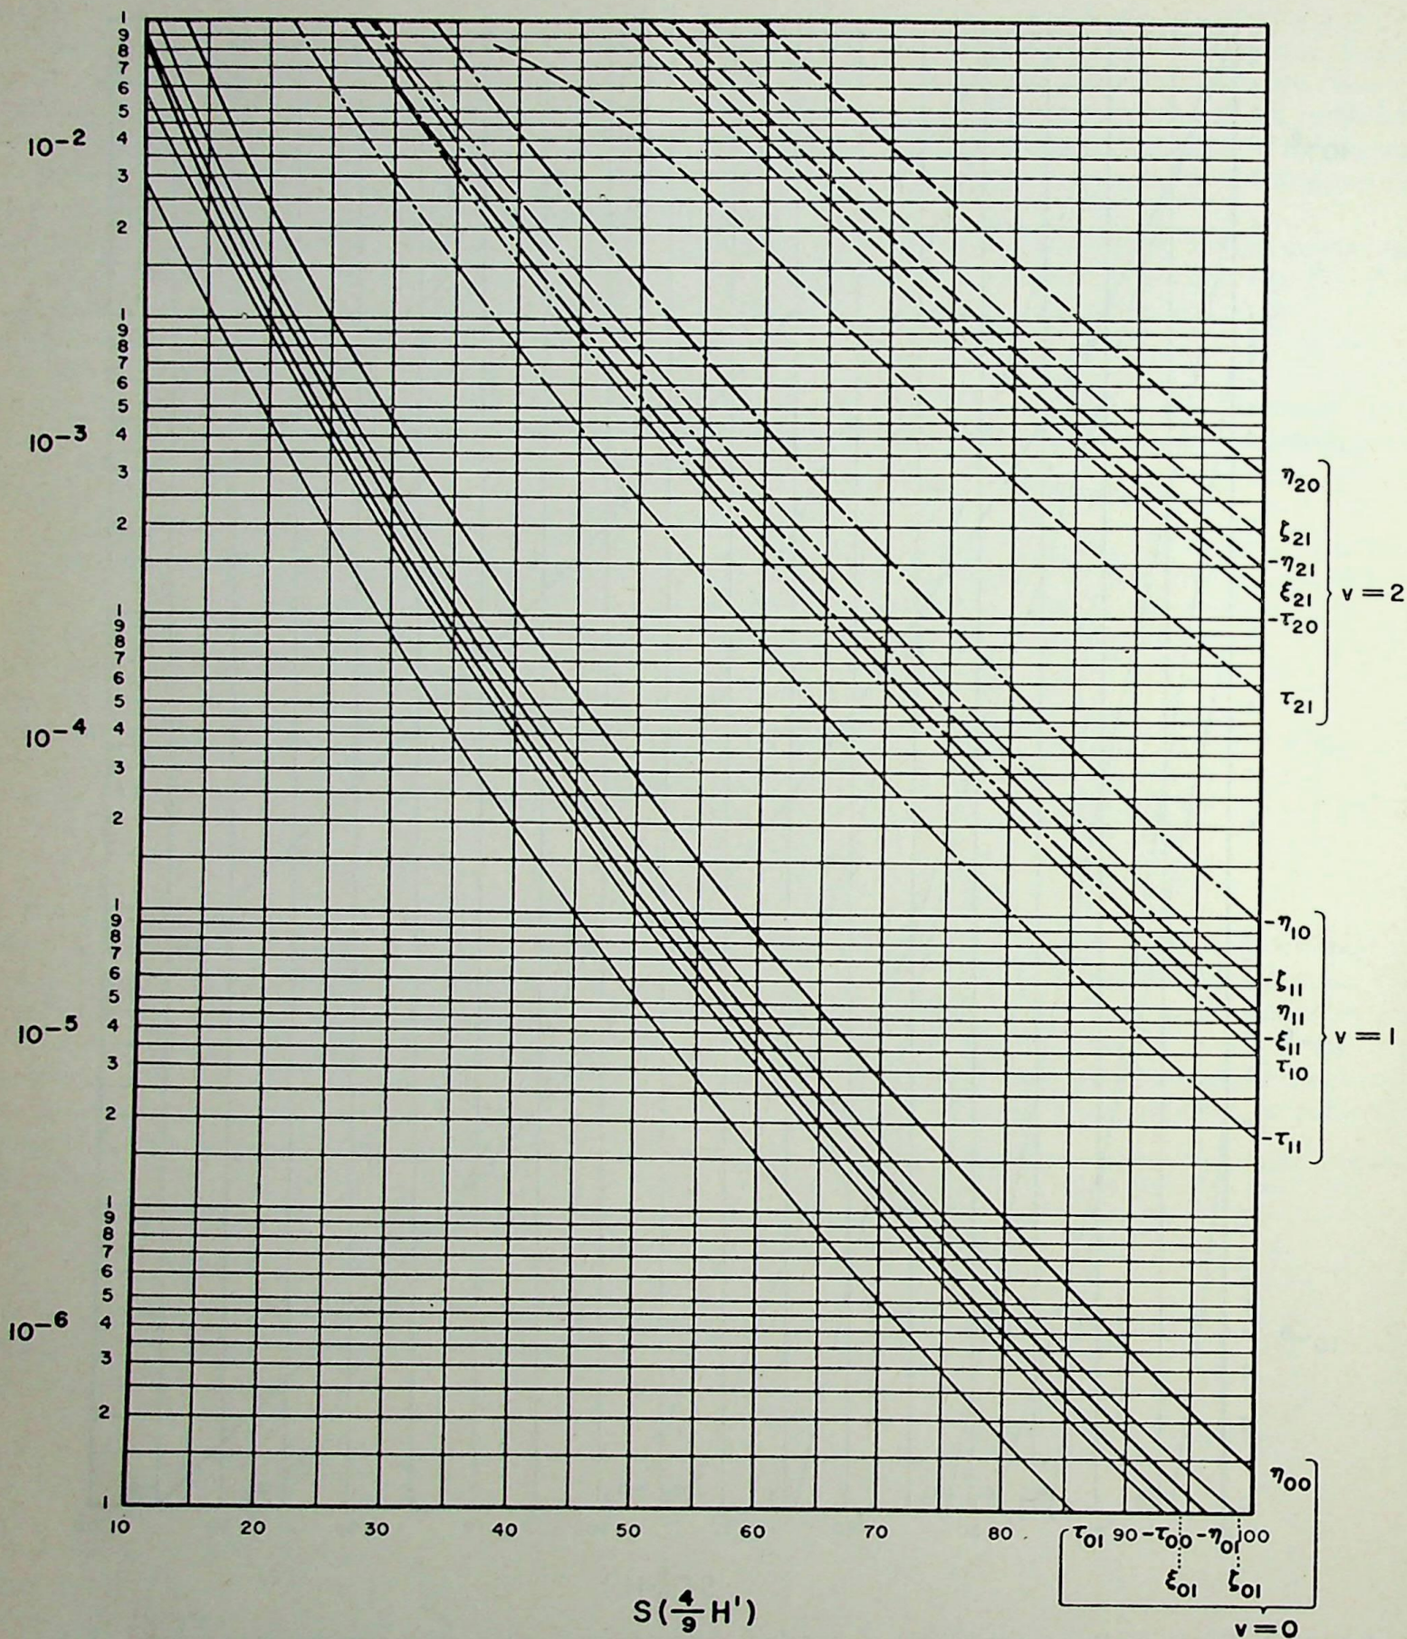

FIG. 8. The power series coefficients as a function of the reduced barrier height s for the various torsional levels [see Eq. (5-5)]. In order to distinguish the various perturbation terms the following notation is used: $w^{(1)}=-2\xi$, $w^{(2)}=\eta$, $w^{(3)}=\zeta$, $w^{(4)}=\tau$. The first subscript denotes the torsional state v, and the second denotes the sublevel σ. ——, $v=0$; —·—, $v=1$; – – – –, $v=2$.

nance of a_1 is seen in Table IV by the fact that the empirical constants B and C have all about the same value for $v=0$. The small deviations are caused by the low s values.

For low values of J, K, and ρ, the agreement between the IAM and PAM is very good. The splittings of the $J=1$ energy levels are given as a comparison in Table V. These results become identical if ρK is small and the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

barrier is high. Under such circumstances Eq. (5-4) can be approximated by the first two terms and $\sin(2\pi/3)\rho K$ may be replaced by $(2\pi/3)\rho K$. A similar agreement between the IAM and PAM is found for the higher J levels.

These connecting relations also indicate the limitations of the two methods: the IAM is restricted to low J because of computational difficulties, and the PAM is restricted to low values of ρK. If J and ρK are large and the asymmetry is small, a method of solution similar to that used by Burkhard and Dennison[8] on methyl alcohol probably would be the best. If J, ρK, and the asymmetry are all large, both the PAM and IAM involve a considerable amount of calculation. As the barrier is lowered, more expansion terms in Eqs. (5-4) and (5-5) are needed to determine the energy levels.

V. Sample Calculation on the Spectrum of Acetaldehyde (CH_3CHO)

Some of the points previously discussed in regard to the determination of the barrier height from the observed spectrum are illustrated by considering acetaldehyde[38] as an example. The values of the parameters obtained in this section differ slightly from the reported values by Kilb *et al.*,[38] because our calculation is not performed to the same refinement as that of reference 38.

Four of the transitions reported in reference 38 for the normal isotopic species are given in Table VI. The estimated unperturbed frequency given in Table VI was taken as $\frac{2}{3}$ of the doublet separation from the A line. For the $2_{12} \leftarrow 1_{11}$ transition and the $2_{11} \leftarrow 1_{10}$ transition, this procedure is not valid because of the δ_1 term. Here the unperturbed position was estimated from the A line alone. For the $2_{12} \leftarrow 1_{11}$ transition two-thirds of the $1_{01} \leftarrow 0_{00}$ splitting was subtracted from the A line; for the $2_{11} \leftarrow 1_{10}$ transition three times this amount was subtracted from the A line. This procedure follows directly from the PAM (see Table I).

In order to evaluate the barrier height from the internal rotation splittings, the bond lengths and the bond angles of the molecule must be known. These can best be determined from the rotational constants of a number of isotopic species of the molecule.[38] In this sample calculation, however, we use an approximate assumed structure for acetaldehyde. The various molecular parameters calculated from this assumed structure are shown in Table VI.

TABLE IV. Approximate formulas (threefold case).
$\mathrm{Log}X = \log A + B\log s - C(s)^{\frac{1}{2}} + Ds$.

X	v	Range of s	Error	A	B	C	D

TABLE V. Comparison of the splitting formulas for an asymmetric molecule with a plane of symmetry.

PAM

$$\Delta E(1_{01}) = \Delta B = F\rho_z^2 \Delta w_v^{(2)}.$$

$$\Delta E(1_{11}) = \Delta C - \frac{(Q_z w_{v1}^{(1)})^2}{A-B} = F\rho_z^2 \Delta w_v^{(2)} - \frac{\delta_1^2}{A-B}.$$

$$\Delta E(1_{10}) = \Delta B + \Delta C + \frac{(Q_z w_{v1}^{(1)})^2}{A-B} = F\rho^2 \Delta w_v^{(2)} + \frac{\delta_1^2}{A-B}.$$

IAM

$$\Delta E(1_{01}) = \Delta_0 + \beta^2(\Delta_1 - \Delta_0) \approx \Delta_0 - \frac{2\pi^2}{9}\rho_z^2 \Delta_0.$$

$$\Delta E(1_{11}) = \Delta_1 - \beta^2(\Delta_1 - \Delta_0) - \frac{\delta_1^2}{A-B} \approx \Delta_0 - \frac{2\pi^2}{9}\rho_z^2\Delta_0 - \frac{\delta_1^2}{A-B}.$$

$$\Delta E(1_{10}) = \Delta_1 + \frac{\delta_1^2}{A-B} \approx \Delta_1 - \frac{2\pi^2}{9}\rho^2\Delta_0 + \frac{\delta_1^2}{A-B}.$$

Connecting relations

$$\beta^2 = \frac{\rho_x^2}{\rho^2}, \quad \alpha^2 = \frac{\rho_z^2}{\rho^2},$$

$$F\Delta w_v^{(0)} = F\Delta b = F(b_A - b_E) = (4/9)\Delta_0 = \tfrac{2}{3}Fa_1,$$

$$-F\Delta w_v^{(2)} = \frac{2\pi^2}{9}\Delta_0 = \frac{\pi^2}{3}Fa_1,$$

$$\Delta_1 - \Delta_0 = \Delta_0\left(\cos\frac{2\pi\rho}{3} - 1\right) \approx -\Delta_0\frac{2\pi^2}{9}\rho^2,$$

$$\delta_1 = +\frac{\alpha\Delta_0}{\sqrt{3}}\sin\frac{2\pi}{3}\rho \approx +\frac{2\pi}{3\sqrt{3}}\rho_z\Delta_0 = \frac{\pi}{\sqrt{3}}\rho_z Fa_1 = F\rho_z w_{v1}^{(1)},$$

$$= Q_z w_{v1}^{(1)} = -2Q_z p_{vv}.$$

A. IAM *Calculations on Acetaldehyde*

From Eqs. (3-56), (3-57), (3-28), and (3-4) we can obtain the expressions for the splitting of the various transitions. For the $J = 1_{01} \leftarrow 0_{00}$ transition a splitting of +3.0 Mc was measured. The approximate formula for this transition is as follows:

$$\nu_A - \nu_E = \Delta\nu = \beta^2(\Delta_1 - \Delta_0) = -0.22134\Delta_0\beta^2$$
$$= -(9/4)F\Delta b\beta^2(0.22134) = -678.5\Delta b \text{ Mc}.$$

By equating this to 3.0 Mc, we obtain a value of -0.004422 for Δb. From the formulas in Table IV, from the curve in Fig. 7 for a_1 ($\Delta b = +2a_1/3$), or from references 3b and 104, the corresponding s value can be determined. A value of 22.943 was obtained which corresponds to a barrier height of 407.7 cm^{-1} (1166 cal/mole). The calculations for the $2_{02} \leftarrow 1_{01}$ follow in a similar manner.

TABLE VI. Parameters for acetaldehyde.

1. Spectrum

	Obs frequency	Estimated unperturbed frequency
$1_{01}-0_{00}$	19 265.3 (*A*) 19 262.3 (*E*)	19 263.3
$2_{12}-1_{11}$	37 464.6 (*A*) 37 687.2 (*E*)	37 462.6
$2_{02}-1_{01}$	38 512.3 (*A*) 38 506.4 (*E*)	38 508.4
$2_{11}-1_{10}$	39 594.9 (*A*) 39 362.5 (*E*)	39 588.9

2. Rotational constants

C (*A*) 56.9 kMc
B (*B*) 10 163.2 Mc
A (*C*) 9100.0 Mc

The rotational constant notation in parenthesis refers to reference 38.

3. Assumed molecular structure

d_{CH}	1.09 *A* (methyl group)	<HCH	108°15′
d_{CC}	1.54	<CCH	120°
d_{CO}	1.21	<CCO	120°
d_{CH}	1.09 (aldehyde group)		

4. Moments of inertia

I_x	55.553 amu A^2	I_{aa}	55.553
I_y	49.742	I_{bb}	43.176
I_z	8.890	I_{cc}	15.086
I_α	3.079	I_{bc}	14.563

5. Internal rotation parameters

λ_y	0.3910	$F=236.9$ kMc$=17.77$ cm^{-1}
λ_z	0.9204	$\Delta_1=0.77866\Delta_0$
r	0.6931	$\Delta_2=0.21262\Delta_0$
β^2	0.00583	
ρ	0.31941	$(2\pi/3)\rho K=38.86$°K

In the calculations of the barrier height from the $2_{12}\leftarrow 1_{11}$ transition and the $2_{11}\leftarrow 1_{10}$ transition, the δ_1 term must also be considered. For the 2_{12} and 2_{11} energy levels we have the following 2×2 matrix (formed by the K and $-K$ state) with the eigenvalues $\pm\lambda_2$:

$$\begin{bmatrix} 190\,400\Delta b & 1594.8 \\ 1594.8 & -190\,400\Delta b \end{bmatrix},$$

where

$$\delta_1=(1/\sqrt{3})\Delta_0\sin(2\pi/3)\rho K=190\,400\Delta b \text{ Mc}$$

from Eq. (3-58);

$$\delta_{Asy}=-\tfrac{1}{4}(A-B)J(J+1)=\tfrac{1}{4}(1063.2)J(J+1),$$

from Eq. (3-59);

and for the 1_{10} and 1_{11} energy levels we have the following matrix with eigenvalues $\pm\lambda_1$:

$$\begin{bmatrix} 190\,400\Delta b & 531.6 \\ 531.6 & -190\,400\Delta b \end{bmatrix}.$$

Here, terms on the diagonal which are common to both states have been omitted. The expression for the splitting in $2_{12}\leftarrow 1_{11}$ transitions from Eq. (3-56) is then

$$\Delta\nu=\beta^2(\Delta_2+2\Delta_0-3\Delta_1)+\delta_1 \text{ terms}$$
$$=378.01\Delta b+(\lambda_2-1594.8)-(\lambda_1-531.6).$$

By equating this to the observed splitting of -222.6 Mc we obtain a Δb of -0.003993 after successive approximations. This leads to a value of 23.56 for s and 418.7 cm^{-1} (1197 cal/mole) for the barrier height. In a similar manner the expression for the $2_{11}\leftarrow 1_{10}$ transition is

$$\Delta\nu=\beta^2(\Delta_2-\Delta_1)+\delta_1 \text{ terms}$$
$$=-1759.0\Delta b-(\lambda_2-1594.8)+(\lambda_1-531.6).$$

By equating this to the observed splitting of $+232.4$ Mc we obtain a Δb of -0.00405. A value of 23.48 is obtained for s and 417.2 cm^{-1} (1193 cal/mole) for the barrier height. These results are compared in Table VII with the results obtained in reference 38 and by the PAM.

B. PAM Calculations on Acetaldehyde

From Table II and Eq. (3-33) we can obtain the expressions for the splittings of the various transitions. The equation for the $1_{01}\leftarrow 0_{00}$ transition is

$$\Delta\nu=\Delta B=\frac{h}{8\pi^2}\frac{\lambda_y{}^2 I_\alpha}{rI_y{}^2}\Delta w_0{}^{(2)}=138.74\Delta w_0{}^{(2)}.$$

By using the approximate formulas in Table IV or the curves in Fig. 8 we obtain an s value of 22.95 and a barrier height of 407.8 cm^{-1} (1166 cal/mole). The transition $2_{02}\leftarrow 1_{01}$ follows in a similar manner.

In order to obtain the splittings for the $2_{12}\leftarrow 1_{11}$ transition and the $2_{11}\leftarrow 1_{10}$ transition it is necessary to diagonalize two 2×2 matrices because of the linear terms in K. These matrices are

$$\begin{bmatrix} -151\,040p_{00}+7680w_{01}{}^{(3)} & 1594.8 \\ 1594.8 & 151\,040p_{00}-7680w_{01}{}^{(3)} \end{bmatrix},$$

and

$$\begin{bmatrix} -151\,040p_{00}+7680w_{01}{}^{(3)} & 531.6 \\ 531.6 & +151\,040p_{00}-7\,680w_{10}{}^{(3)} \end{bmatrix}.$$

TABLE VII. Barrier height in acetaldehyde by various methods.

	IAM	PAM	KLW (38)
$1_{01}-0_{00}$	407.7 cm^{-1}	407.8	408.9
$2_{02}-1_{01}$	409.7	410.1	[b]
$2_{12}-1_{11}$	418.7	418.0	417.3
$2_{11}+1_{10}$	417.2	418.0	419.0
δ_1	-765 Mc	-763 Mc[a]	-760 Mc[c]
V_3 (av)	414 cm^{-1}		

[a] The third-order correction included.
[b] No individual value was reported for this transition in reference 38.
[c] A sixfold potential energy term was included. See the footnote at the end of Sec. 3 II.A3(b).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Here the third-order terms have been included. The expressions for the $2_{12} \leftarrow 1_{11}$ transition and for the $2_{11} \leftarrow 1_{10}$ transition from Table II are

$$\Delta\nu = \Delta B + (\lambda_2 - 1594.8) - (\lambda_1 - 531.6)(2_{12} \leftarrow 1_{11}),$$
$$\Delta\nu = 3\Delta B - (\lambda_2 - 1594.8) + (\lambda_1 - 531.6)(2_{11} \leftarrow 1_{10}).$$

By equating these to the observed splittings we obtain the following parameters after successive approximations:

$$p_{00} = 5.46 \times 10^{-3} \qquad Q_z w_{01}^{(1)} = -824.7 \text{ Mc}$$
$$\Delta w_0^{(2)} = 1.92 \times 10^{-2} \qquad \Delta B = 2.66 \text{ Mc}$$
$$w_{01}^{(3)} = 8.10 \times 10^{-3} \qquad F(Q_z/F)^3 w^{(3)} = 62.2 \text{ Mc}.$$

From the curves in Fig. 8 or the approximate formulas in Table IV, a value of 23.52 is obtained for s which corresponds to a barrier height of 418.0 cm^{-1} (1195 cal/mole). The results are summarized in Table VII.

6. SELECTION RULES AND NUCLEAR SPIN STATISTICS

I. Selection Rule for Symmetric Molecules

The selection rules for symmetric molecules can be derived easily from the wave function of the internal rotor. Consider, for instance, the wave function obtained from the IAM

$$S_{JKM}(\theta,\varphi) e^{iK\chi} e^{-ip_K \alpha} P_{K\nu\sigma}(\alpha).$$

Since the orientation of the dipole moment is independent of the angle α, the usual selection rules for the dipole radiation of a rigid symmetric rotor are applicable, i.e.,

$$\Delta J = 0, \pm 1; \quad \Delta K = 0.$$

In addition, it may be shown from Eq. (3-25) that the transition moments are different from zero only when $\Delta\sigma = 0$.

II. Selection Rules for Asymmetric Molecules

The selection rules for an asymmetric molecule in the quantum number J is $\Delta J = 0, \pm 1$. This follows from the fact that the total angular momentum for a rotating molecule remains a good quantum number even when internal rotation is present. The selection rules governing the changes of the other quantum numbers are more complicated. In general, these rules can be derived by group-theoretical methods.

The general selection rules are derived from symmetry considerations. Application of these rules to the cases of high barrier and low barrier are then discussed in detail.

A. General Selection Rules

The Hamiltonian of a rigid asymmetric rotor is invariant under the operations

$$\begin{aligned} E&: P_x \to P_x,\ P_y \to P_y,\ P_z \to P_z, \\ C_z&: P_x \to -P_x,\ P_y \to -P_y,\ P_z \to P_z, \\ C_x&: P_x \to P_x,\ P_y \to -P_y,\ P_z \to -P_z, \\ C_y&: P_x \to -P_x,\ P_y \to P_y,\ P_z \to -P_z, \end{aligned} \tag{6-1}$$

and therefore has the symmetry of the four group¶¶¶¶ V.

When the effect of internal rotation is included, the Hamiltonian is no longer invariant under the operations given in (6-1) because of the cross terms between the P's and p [e.g., Eq. (2-25) or Eq. (2-37)] or between the P's and functions of the angle α [e.g., Eq. (2-29) or Eq. (2-31)]. The group properties of the various types of molecules are discussed in the following sections.

1. Molecules with a planar frame.—The Hamiltonian Eq. (2-31) or Eq. (2-37) (with $Q_x = 0$) is invariant under the following operations:

$$\begin{aligned} E&: P_{x,y,z} \to P_{x,y,z},\ \alpha \to \alpha(p \to p), \\ C_x&: P_x \to P_x,\ P_{y,z} \to -P_{y,z},\ \alpha \to -\alpha(p \to -p), \\ C_3&: P_{x,y,z} \to P_{x,y,z},\ \alpha \to \alpha + (2\pi/3)(p \to p), \\ C_3^2&: P_{x,y,z} \to P_{x,y,z}, \\ &\qquad \alpha \to \alpha + (4\pi/3) = \alpha - (2\pi/3)(p \to p). \end{aligned} \tag{6-2}$$

(The operations $C_x C_3$ and $C_x C_3^2$ follow directly from these operations.) These symmetry operations satisfy the properties of the group D_3, and therefore the wave functions have the symmetry of the species A_1, A_2, or E.

For this type of molecule the dipole moment lies on the plane of the framework and has the transformation properties of A_2. The selection rules for the dipole transitions are then[20]

$$A_1 \leftrightarrow A_2, \quad E \leftrightarrow E.$$

2. Molecules with no symmetry in their framework.—For this class of molecules only the operations E, C_3, C_3^2 leave the Hamiltonian unaltered. The energy states then fall into the species A or E of the C_3 group. Since the dipole moment has the symmetry property of A, the selection rules can be summarized as $A \leftrightarrow A$, $E \leftrightarrow E$.

3. Molecules with a frame of C_{2v} symmetry (CH_3NO_2 *type*).[121]—The group properties are of particular interest because the cross term between **P** and p appears only as pP_z. The Hamiltonian is now invariant under the following operations:

$$\begin{aligned} E&: P_{x,y,z} \to P_{x,y,z},\ \alpha \to \alpha(p \to p), \\ C_x&: P_x \to P_x,\ P_{y,z} \to -P_{y,z},\ \alpha \to -\alpha(p \to -p), \\ C_y&: P_y \to P_y,\ P_{x,z} \to -P_{x,z},\ \alpha \to -\alpha(p \to -p), \\ C_z&: P_z \to P_z,\ P_{x,y} \to -P_{x,y},\ \alpha \to \alpha(p \to p). \end{aligned} \tag{6-3}$$

Because of the sixfold symmetry, the Hamiltonian is also invariant under the operation $\alpha \to \alpha + (2n\pi/6)$.

¶¶¶¶ The operation $P_x \to -P_x$, $P_y \to P_y$, $P_z \to P_z$, does not alter the Hamiltonian but does change the commutation relations between the three components of the angular momentum, so it is not considered to be a symmetry operation.

TABLE VIII. Character table for the point group D_{6h}.

	E	$2C_3$	$3C_2C_3$	C_2	$2C_2C_3$	$3C_yC_3$	C_2	$2C_6$	$3C_2C_6$	C_2C_2	$2C_2C_6$	$3C_yC_6$
A_e	1	1	1	1	1	1	1	1	1	1	1	1
B_{ze}	1	1	−1	1	1	−1	1	1	−1	1	1	−1
E_{1e}	2	−1	0	2	−1	0	2	−1	0	2	−1	0
B_{xe}	1	1	1	−1	−1	−1	1	1	1	−1	−1	−1
B_{ye}	1	1	−1	−1	−1	1	1	1	−1	−1	−1	1
E_{2e}	2	−1	0	−2	1	0	2	−1	0	−2	1	0
A_0	1	1	1	1	1	1	−1	−1	−1	−1	−1	−1
B_{z0}	1	1	−1	1	1	−1	−1	−1	1	−1	−1	1
E_{10}	2	−1	0	2	−1	0	−2	1	0	−2	1	0
B_{x0}	1	1	1	−1	−1	−1	−1	−1	−1	1	1	1
B_{y0}	1	1	−1	−1	−1	1	−1	−1	1	1	1	−1
E_{20}	2	−1	0	−2	1	0	−2	1	0	2	−1	0

These six operations are denoted by E, C_6, $C_6^2(C_3)$, $C_6^3(C_2)$, $C_6^4(C_3^2)$, and C_6^5, where the operation C_6 represents $\alpha \rightarrow \alpha + (\pi/3)$. These six operations along with the "four-group" operations form a new group of twenty-four elements which is isomorphous to the point group D_{6h}. The character table of this group is given in Table VIII.

The dipole moment for this model would ordinarily be along the z axis. If this is the case, the transition moment will have symmetry B_{ze}. The selection rules for dipole absorption will then be $A_e \leftrightarrow B_{ze}$, $B_{xe} \leftrightarrow B_{ye}$, $E_{1e} \leftrightarrow E_{1e}$, $E_{2e} \leftrightarrow E_{2e}$, $A_0 \leftrightarrow B_{z0}$, $B_{x0} \leftrightarrow B_{y0}$, $E_{10} \leftrightarrow E_{10}$, $E_{20} \leftrightarrow E_{20}$.

B. Selection Rules for High Barrier

Molecules with a planar frame may be considered as an example. The limiting rigid-rotor Hamiltonian belongs to the four-group. As the operation C_x is common to both the D_3 group (of the torsional rotor) and the four-group, the A_1 species of the D_3 group corresponds to A and B_x in the four-group while the A_2 levels of the hindered rotor reduces to the B_y or B_z levels of the limiting rigid molecule. As shown before, the selection rules for the rotational states associated with the nondegenerate torsional levels are $A_1 \leftrightarrow A_2$. In terms of the transitions for the limiting rigid rotor these correspond to A, $B_x \leftrightarrow B_y$, B_z, which are indeed the selection rules for a rigid asymmetric top molecule with dipole moment on the yz plane. Hence, for the internal rotor with high barriers the selection rules governing the transitions between the rotational levels belonging to the nondegenerate torsional levels (the pseudo-rigid rotor lines) may simply be taken as those for the corresponding rigid molecules.

In the case of degenerate torsional levels, according to the general symmetry selection rule $E \leftrightarrow E$, transitions between all the E levels are, in general, possible. This can be understood by considering the effective rotational Hamiltonian for a given torsional level. For the E levels the nonrigid-rotor terms, δ_k, tend to eliminate the asymmetry and the transitions approach those of a symmetric rotor. The eigenfunctions no longer have the symmetry of the four-group, and the symmetry selection rules for the wave functions associated with these symmetry species are not applicable. For the case of high barriers and low K, it may be expected that the transitions in the hindered rotor which are forbidden for the limiting rigid rotor are usually weak. However, if transitions involving higher K values are observed, the effect of the internal rotation can now exceed the asymmetry splitting even in the case of relatively high barriers, and the spectrum becomes very interesting. Consider the perpendicular type transition ($\Delta K = \pm 1$) between two groups of four energy levels corresponding to the A and E levels of a K doublet. At low values of K four lines are expected (two doublets) similar to those shown in Fig. 4. As K increases, all four E transitions are possible and six lines appear (two A and four E). At high values of K the wave function may be approximated by the symmetric top wave function. When this is the case the two A levels of a given K become nearly degenerate and the two A lines merge into a single line. The two E levels, however, remain separated because of the linear term P_z in the effective Hamiltonian Eq. (3-33), and two of the four E lines now become forbidden so that for large values of K one observes a group of three spectral lines—(one A and two E). Such a transition from four lines (low K) to three lines (for high K) has indeed been found by Herschbach and Swalen.[27] In the transition region between these two patterns all four E transitions are observed. Those transitions forbidden in the limit of a rigid rotor can be seen to increase in intensity at the expense of the rigid-rotor lines until finally the triplet pattern results (see Fig. 5).

C. Selection Rules for Low Barrier

So far the only molecules which have been found by the methods of microwave spectroscopy to have low potential barriers to internal rotation are CH_3NO_2 and CH_3BF_2*****; our present discussion is confined mainly to this class of molecules. The symmetry selection rules have been given in Sec. A3. In order to apply these rules to the analysis of the microwave spectrum it is necessary to establish some correlation between the symmetry properties and the rotational quantum numbers.

1. Limiting free rotator.—The Hamiltonian and the energy levels were discussed in Sec. 4. Since the quantum number m is diagonal, the wave function can be expressed as a product of $e^{im\alpha}$ and a function of θ, Φ, and χ. This function may be determined from the transformation matrix which diagonalizes the energy matrix in Eq. (4-13). An inspection of the structure of this matrix reveals the fact that a typical wave function has one of the following forms:

$$\Psi_m^{\text{even } K} = e^{im\alpha} \sum_{\text{even } K} a_K S_{JKM}(\theta,\varphi) e^{iK\chi}, \qquad (6\text{-}4)$$

$$\Psi_m^{\text{odd } K} = e^{im\alpha} \sum_{\text{odd } K} a_K S_{JKM}(\theta,\varphi) e^{iK\chi}, \qquad (6\text{-}5)$$

***** Recently $CH_3C{\equiv}CCH_2Cl$[53a] has been studied and reported to have a low barrier.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where $S_{JKM}(\theta,\varphi)e^{iK\chi}$ denotes the symmetric top wave function and the summation in K in Eqs. (6-4) and (6-5) extends only from $-J$ to J. As explained in Sec. 4, each energy level with $m\neq 0$ is doubly degenerate. This double degeneracy occurs because the energy matrix Eq. (4-13) remains unchanged when m and K are replaced by $-m$ and $-K$. Now those energy levels where m is a multiple of three (and not zero) are associated with the pairs of symmetry species: A_e, B_{ze}; A_0, B_{z0}; B_{xe}, B_{ye}; or B_{x0}, B_{y0}. Here each pair constitutes the double degeneracy which would be split by a barrier. Those energy levels where m is not a multiple of three are associated with the symmetry species: E_{1e}, E_{2e}, E_{10}, E_{20}. Here the degeneracy is not split by the barrier.

Consideration of the C_z operation ($\chi\rightarrow\chi+\pi$) shows that the wave function Eq. (6-4) remains unchanged, but the wave function Eq. (6-5) changes sign. For the C_6^3 operation ($\alpha\rightarrow\alpha+\pi$) both Eq. (6-4) and Eq. (6-5) remain unchanged if m is even but change sign if m is odd. With the aid of the character Table VI, the symmetry properties of the energy levels characterized by different m and K may be summarized as follows:

	$m(m\neq 0)$	K
A_e, B_{ze}, E_{1e}	even	even
B_{xe}, B_{ye}, E_{2e}	even	odd
A_0, B_{z0}, E_{10}	odd	even
B_{x0}, B_{y0}, E_{20}	odd	odd

The selection rules for m and K are such that the parity is not changed. For the quantum number m the selection rule is even more restricted in the case of free rotation. Since the dipole moment is independent of α and neither wave function Eq. (6-4) nor Eq. (6-5) involve states of different m, we have the selection rule $\Delta m=0$. For the K quantum number, the selection rule is $\Delta K=0$, ± 2, ± 4, etc. Here K is nearly a good quantum number and the transitions with $\Delta K=0$ will in general be stronger than those with $\Delta K=\pm 2, \pm 4$, etc. These latter types of transitions result from a mixing of the K levels in Eqs. (6-4) and (6-5). Note, however, that the Wang functions are no longer the appropriate zero-order wave functions because of the linear term in K on the diagonal of the energy matrix.

The discussion presented above pertains to the energy levels with $m\neq 0$ only. When $m=0$, the exponential factor $e^{im\alpha}$ in Eqs. (6-4) and (6-5) and also the linear term in K in the energy matrix disappear. The secular equation degenerates into that of a rigid rotor. Since the expressions in Eqs. (6-4) and (6-5) with $m=0$ are invariant under the operation C_6^3 and C_3, the energy levels with $m=0$ have the symmetry properties of A_e, B_{xe}, B_{ye}, or B_{ze}. The selection rules for the transitions with this series of energy levels are identical to those for a rigid asymmetric top, i.e., $A_e\leftrightarrow B_{ze}$ and $B_{xe}\leftrightarrow B_{ye}$.

2. Low barrier.—As explained in Sec. 4, the addition of a small barrier term $\frac{1}{2}V_0(1-\cos 6\alpha)$ to the Hamiltonian of a free internal rotor does not greatly alter the spacing of the rotational energy levels except for the ones with m equal to whole multiples of three. The nondiagonal elements in m may be removed by a Van Vleck transformation so that the secular equation can be factored approximately into blocks corresponding to different values of m. The basis functions for this effective energy matrix (for $m\neq 3n$) are then

$$(e^{im\alpha}+ae^{i(m+6)\alpha}+be^{i(m-6)\alpha}+\cdots)S_{JKM}(\theta,\varphi)e^{iK\chi}. \quad (6\text{-}6)$$

The coefficients a and b do not depend critically on K. The final composite wave functions are taken as linear combinations of such basis functions. The structure of the secular Eq. (4-19) again is such that the basis functions of odd and even K do not combine in forming the final wave function. Furthermore, since the coefficients a, b are usually very small, one may still use m as the labeling index for the energy states. The selection rule for m is Δm equals a whole multiple of 6. Since the $\Delta m\neq 0$ transitions are weak and usually beyond the microwave region, the selection rules for the dipole transitions may be given approximately as $\Delta m=0$, $\Delta K=0$, $\Delta J=0, \pm 1$. Here again it is assumed that K is nearly a good quantum number. Remembering that each energy level characterized by (m,K) is degenerate with the one by $(-m,-K)$, one may easily show that the selection rules $\Delta m=6n$ (n being an integer) are equivalent to those derived from the symmetry consideration.

For $m=3$ (or whole multiple of three) the solution of the secular equation becomes more complicated as discussed in Sec. 4 II. As an example the block in the secular equation corresponding to $J=1$, $m=3$, odd K was given in Eq. (4-21). This secular equation can be factored by choosing as the basis functions the type of linear combination given in Eq. (4-22) i.e.,

$$\psi(K,m=3)\pm\psi(-K,m=-3). \quad (6\text{-}7)$$

To the zeroth-order approximation these functions may be expressed as

$$e^{3i\alpha}S_{JKM}(\theta,\varphi)e^{iK\chi}\pm e^{-3i\alpha}S_{J-KM}(\theta,\varphi)e^{-iK\chi}. \quad (6\text{-}8)$$

These two linear combinations have the symmetry property of the A_0 and B_{z0} when K is even; and B_{x0} and B_{y0} for odd K. In the case of the example in Eq. (4-21) the energy eigenfunctions arising from the secular Eq. (4-23a) have the symmetry of B_{z0} while those corresponding to the determinant Eq. (4-23b) belong to A_0 species. The approximate wave functions for these four states are

$$\begin{aligned}
\Psi_{++}&=a[\psi(1,3)+\psi(-1,-3)]\\
&\quad+b[\psi(-1,3)+\psi(1,-3)],\\
\Psi_{+-}&=-b[\psi(1,3)+\psi(-1,-3)]\\
&\quad+a[\psi(-1,3)+\psi(1,-3)],\\
\Psi_{-+}&=c[\psi(1,3)-\psi(-1,-3)]\\
&\quad+d[\psi(-1,3)-\psi(1,-3)],\\
\Psi_{--}&=-d[\psi(1,3)-\psi(-1,-3)]\\
&\quad+c[\psi(-1,3)-\psi(1,-3)].
\end{aligned} \quad (6\text{-}9)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Here the first and second number inside the parentheses of the functions refer to the values of K and m, respectively. For CH_3NO_2 the difference between the two diagonal elements in Eq. (4-23a) and Eq. (4-23b) are roughly ten times greater than the off-diagonal terms; so the ratios of the coefficients a, b, c, and d in Eq. (6-9) may be estimated by perturbation methods as $|a/b| \approx |c/d| \approx 10$. One may construct four approximate wave functions similar to Eq. (6-9) for the states with $J=2, m=3$, and odd K. The coefficients a, b, c, etc., here are somewhat different from those in Eq. (6-9), but the ratios of these coefficients are still of the same order of magnitude as those for $J=1$. In accordance with the symmetry selection rules $A \leftrightarrow B_z$, $B_x \leftrightarrow B_y$, $o \leftrightarrow o$, $e \leftrightarrow e$, derived previously, there are eight possible transitions for $J=2 \leftarrow 1, m=3$ with odd K. Among these eight lines, four are much more intense than the others, and indeed only the four strong lines are observed in the microwave spectrum. These transitions are

$$\Psi_{++} \leftrightarrow \Psi_{++}, \quad \Psi_{+-} \leftrightarrow \Psi_{+-}, \quad \Psi_{-+} \leftrightarrow \Psi_{-+}, \quad \Psi_{--} \leftrightarrow \Psi_{--}.$$

Similar results are also found in the microwave spectrum of CH_3BF_2.

The selection rules for the transitions involving the energy levels with $m=0$, are $A_e \leftrightarrow B_{ze}$, and $B_{xe} \leftrightarrow_{ye}$.

III. Nuclear Spin Weight

To obtain the relative intensities of the components of the internal rotation multiplets (such as the doublet for the high barrier case), the correct combinations of nuclear spin functions ψ_s with the internal torsional function ψ_t must be found. The method for finding such appropriate nuclear spin functions has been given by Wilson.[118] This procedure will be applied to the various types of nonsymmetric molecules.

A. Molecules with No Symmetry

By following Wilson,[118] we observe that for the protons in the methyl radical, the group of permutation operations which are equivalent to the internal rotations of the molecules is isomorphous with the group C_3, as is the group derived from the internal rotation operations. For CH_3 there are eight nuclear spin functions which can be schematically represented by specifying the quantum number m_s for each nucleus as follows:

$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	(one)
$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$ etc.	(three)
$\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$ etc.	(three)
$-\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	(one)

These eight spin functions form a reducible representation of the C_3 group. The characters of this representation are $\chi(E)=8$, $\chi(C_3)=2$, $\chi(C_3^2)=2$. This reducible representation then belongs to the species $4A+2E_1+2E_2$.[38] The over-all wave function must be antisymmetric to the interchange of protons, i.e., of species A with respect to the operations of C_3. Since the nondegenerate torsional function is of species A, the symmetry of the composite wave functions is $A \cdot (4A+2E_1+2E_2) = 4A+2E_1+2E_2$; therefore, the statistical weight is four. For the degenerate torsional sublevel the reducible representation formed by the total wave function is $(E_1+E_2) \cdot (4A+2E_1+2E_2) = 4A+6E_1+6E_2$. Consequently the members of a torsional doublet (in the case of high barriers) of a particular rotational transition should have equal intensity.

The twenty-seven nuclear spin states for a CD_3 group form a representation of species $11A+8E_1+8E_2$.[38] Thus the nondegenerate levels yield $A \cdot (11A+8E_1+8E_2) = 11A+8E_1+8E_2$, whereas the degenerate levels give rise to $(E_1+E_2) \cdot (11A+8E_1+8E_2) = 16A+19E_1+19E_2$. The relative intensity of the two members of a doublet is therefore 11/16.

This discussion is also applicable to the molecules with a planar frame such as acetaldehyde.

B. CH_3NO_2 Type Molecules

The method outlined in the previous section may also be applied to find the statistical weights of the degenerate and the nondegenerate levels for this type of molecule. When the barrier is low the separation between the nondegenerate level and a degenerate level—say between a level with $m=0$ and one with $m=1$—is of the order $2Fm$ which may be comparable to kT. Hence the relative intensity of the various members of the multiplet arising from the internal rotation is not simply equal to the ratio of the statistical weights. Rather, the Boltzmann factor must be taken into consideration.

In addition, for the case of CH_2NO_2[16] the wave function must be even with respect to the interchange of the two oxygen ($I=0$). This operation is $C_zC_6^3$. Thus, only the levels with symmetry properties of A_e, B_{ze}, E_{1e}, B_{x0}, B_{y0}, E_{20}[107] can exist in CH_3NO_2[16]. For CH_3BF_2 these species will have one-third the statistical weight of the others because of the fluorine nuclear spin ($I=\frac{1}{2}$) and the requirement of antisymmetry for exchange of the two fluorine nuclei.[121 75].

7. VIBRATION-TORSION-ROTATION INTERACTION

The methods for the determination of the potential barrier described in Secs. 3 and 5 utilize the splittings between the same rotational transitions corresponding to the two ground torsional levels. These methods, however, fail when the splittings of the rotational lines vanish as in the case of symmetric tops (see Fig. 4) or fall below the limit of resolution of the spectrograph for very high barriers. The latter difficulty may be overcome, at least partially, by measuring the splittings of the rotational lines in the excited torsional levels (satellites) which are considerably larger than those in the ground torsional state. Because of the influence of the molecular vibrations on the internal torsion and the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

over-all rotation, these satellites are shifted from the "main lines" (the lines associated with the ground torsional state). Furthermore, the splittings of the satellites sometimes contain sizeable contributions from the effect of molecular vibration (cf. Sec. 5 II) as well as the internal rotation. With a careful analysis of the interaction of vibration, torsion, and over-all rotation, it is possible to determine the barrier height either from the splittings of the satellites or from the shifts of the satellites from the main line. The latter procedure is particularly significant because it is applicable to symmetric top molecules.

Besides the frequency shifts, the intensities of the satellites are decreased by the Boltzmann factor. From the intensity ratios between the satellites and the main line, one can calculate the energy differences between the ground and excited torsional states from which the barrier height may be determined.

In the present section two methods—the satellite frequency pattern and the relative intensities—for determining potential barriers are presented. Neither of these methods gives as accurate results as the "splitting method" described in the previous sections. Therefore, these methods are used only when the splitting method fails to yield the barrier height or when an analysis of the torsional satellites is desired to study torsion-rotation interaction.

I. Satellite Frequency Pattern

In the discussion of the theory of internal rotation in Sec. 2 the effects of molecular vibration have not been considered. This is justified if the torsional frequency is well below the frequencies of the other vibrations. Since the moments of inertia do not depend directly on the torsional normal coordinate, the only way the torsional mode can affect the moments of inertia is by means of higher-order interactions via the other vibrations of the molecule.[42] When the nonrigidity of the two halves of the molecule is taken into account, some interesting results are obtained. Consider first the symmetric molecules such as methyl silane, CH_3SiH_3. Classically, as the CH_3 group oscillates about its equilibrium position, the centrifugal force produces a slight change in the molecular dimensions. Because both the angular velocity and the potential energy are functions of the internal angles α, the instantaneous configuration of the molecule depends also on α. The rotational constant B determined from the microwave spectra is actually related to the average value of the reciprocal of the moment of inertia for a given torsional and vibrational state. One would expect that the rotational constants and thus the rotational lines associated with the different excited torsional states would be shifted by different amounts (even for the case of a symmetric top). From the pattern of these lines one can then determine the height of the potential barrier. Furthermore, this type of internal torsion-vibration interaction also gives rise to an additional splitting of the pairs of lines associated with the A and E sublevels of a *given* torsional level; but as shown by Kivelson,[42] such a splitting for the ground torsional state of CH_3SiH_3 is less than 0.05 Mc which is experimentally unobservable.

The quantum-mechanical treatment can be carried out in this way: The Hamiltonian, including the rotation, internal torsion, and vibration,††††† according to Kivelson,[42,45b] is written as

$$H=\tfrac{1}{2}\sum_{ij}\mu_{ij}P_iP_j+H_T+H_v, \qquad (7\text{-}1)$$

where P_i is the component of the total angular momentum along the i principal axis, μ_{ij} is the ij component of the inverse of the instantaneous inertia tensor and H_T and H_v represent the part of the Hamiltonian connected with the internal torsion and vibration, respectively. A Van Vleck transformation[34] similar to that used by Howard and Wilson[120] is applied to remove the nondiagonality in the vibrational quantum number v. The results may be expressed approximately as

$$H=W_v+\tfrac{1}{2}\sum_{ij}(v|\mu_{ij}|v)P_iP_j+(v|H_T|v)$$
$$+\sum_{v'}{}'|(v|\tfrac{1}{2}\sum_{ij}\mu_{ij}P_iP_j+H_T|v')|^2(W_v-W_{v'})^{-1}. \qquad (7\text{-}2)$$

The first term W_v, the vibrational energy, represents merely an additive constant and can be safely dropped. If only the splittings of the rotational lines in various torsional states are desired, then the terms independent of the rotational quantum numbers can be neglected. Finally, the terms corresponding to the ordinary centrifugal distortion effect can usually be ignored. By using Eq. (7-2) as the Hamiltonian, Kivelson[42] calculated the effective rotational constant B for a symmetric rotor and arrived at the equation

$$B_{v\sigma}=B_v+F_v(Kv\sigma|1-\cos3\alpha|Kv\sigma)+G_v(Kv\sigma|p'^2|Kv\sigma)$$
$$+L_vK(Kv\sigma|p'|Kv\sigma), \qquad (7\text{-}3)‡‡‡‡‡$$

where p' is the angular momentum associated with the torsional motion as defined in Eq. (2-8), B_v is the effective rotational constant averaged over the vibrational functions, and F_v, G_v, and L_v are empirical constants which depend on the interaction of the vibrations and the internal torsion. It is now possible to modify Eq. (7-3) slightly in order to see clearly the difference between this expression and the familiar one for ordinary vibrations. The torsional equation in reduced form is

$$\left[p'^2+\frac{9s}{8}(1-\cos3\alpha)\right]P_{Kv\sigma}=(9/4)b_{v\sigma}P_{Kv\sigma}. \qquad (7\text{-}4)$$

††††† Here the word "vibration" means all the internal modes of motion other than the hindered rotation.

‡‡‡‡‡ Kivelson[42] used the quantum number m for $Kv\sigma$ and Π_2 for $p'=p-\rho P_z$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In this equation the kinetic and potential energy may be identified

$$\langle T\rangle=(Kv\sigma|p'^2|Kv\sigma)$$

$$\langle V\rangle=\frac{9s}{8}(Kv\sigma|1-\cos 3\alpha|Kv\sigma).$$

For $K=0$ Eq. (7-3) becomes

$$B_{v\sigma}=B_v+F_v'\langle V\rangle+G_v\langle T\rangle, \qquad (7\text{-}5)$$

where

$$F_v'=8F_v/9s;$$

or

$$B_{v\sigma}=B_v-\beta_1\langle H\rangle-\beta_2[\langle T\rangle-\langle V\rangle], \qquad (7\text{-}6a)$$

$$=B_v-(9/4)\beta_1 b_{v\sigma}-\beta_2 x_{v\sigma}, \qquad (7\text{-}6b)$$

where

$$\beta_1=-\tfrac{1}{2}(G_v+F_v'), \quad x_{v\sigma}=\langle T\rangle-\langle V\rangle,$$
$$\beta_2=-\tfrac{1}{2}(G_v-F_v'), \quad \langle H\rangle=\langle T\rangle+\langle V\rangle=(9/4)b_{v\sigma}.$$

Now for harmonic vibrations

$$\langle T\rangle=\langle V\rangle,$$

and the asymptotic form for b_v as $s\rightarrow\infty$ is $b_v\sim 2(s)^{\frac{1}{2}}\times(v+\frac{1}{2})$. It follows that

$$B_{v\sigma}=B_v-\alpha_T(v+\tfrac{1}{2}), \qquad (7\text{-}7)^{29}$$

where

$$\alpha_T=(9/2)(s)^{\frac{1}{2}}\beta_1.$$

For the $J=1\leftarrow 0$ transition of CH_3SiH_3 Kivelson found

$$F_v=-65.322 \text{ Mc} \quad \text{and} \quad G_v=-0.8824 \text{ Mc},$$
$$s=30.22 \ (\alpha=17.0=\tfrac{9}{16}s),$$

and therefore $F_v'=-1.9212$ Mc, $\beta_1=+1.4018$ Mc, $\beta_2=-0.5194$ Mc, and $\alpha_T=+34.68$ Mc. For an ordinary vibration, the constant α is of the order B_e^2/ω which is ~ 22 Mc. Consequently, we see that this analysis is very similar to that for ordinary vibration rotation interaction; only the extreme departure from harmonicity must be corrected by the β_2 term.

Kivelson's method of analysis has also been extended to include asymmetric molecules[43,44,45b] and the Stark effect.[45a] Application of this theory has been made in the study of the vibration-torsion interaction of methyl alcohol,[77] methyl mercaptan[49,50a] and propylene oxide[27] (cf. Fig. 6).

Hecht and Dennison[21] have also investigated the nonrigidity effects in methyl alcohol. In addition to the centrifugal stretching, these authors point out that the effect of Coriolis force (from the internal motion) on the distortion of the equilibrium configuration of the molecule should also be considered. While the OH group executes the internal torsion, the Coriolis force arising from the end-over-end rotation of the entire molecule causes the hydrogen atom to rock back and forth on the COH plane. The effect is to produce a change in the average moments of inertia (over one external revolution) which, analogous to the distortion by centrifugal force described in the beginning of this section, depends on the torsional state. Hecht and Dennison[21] also take into account the fact that the height of the barrier is a function of the molecular dimension.[43] Inasmuch as the origin of the barrier is not clearly understood, the dependence of the barrier height on the displacements of the atoms cannot be calculated in any simple way; it can best be described in a parametric form as

$$V=V_3[1+\textstyle\sum_i\alpha_i\delta_{q_i}+\cdots] \qquad (7\text{-}8)$$

where the δ_{q_i} are the displacements of the atoms. A rigorous theoretical treatment which takes into consideration the effects of centrifugal and Coriolis forces on the average rotational constants as well as the change of potential barrier height could become very lengthy because of the large number of normal vibrations which could effect the moments of inertia through Coriolis interaction. Hecht and Dennison[21] carried out the calculation in two steps. They first examined the interaction between the rotation and the normal vibration in which the O—H bar moves in its own plane relative to the methyl group. In other words, they used a relatively simple model for CH_3OH which has five degrees of freedom—three for over-all rotation, one for internal torsion, and one for the O—H rocking. All the other modes of vibration were considered to be frozen. In the second step the remaining normal vibrations were introduced as perturbation and the effects of these additional terms on the energy levels were investigated with the aid of appropriate approximations. As the vibrational frequencies of methyl alcohol can be obtained from the vibrational spectrum, and the potential barrier height has been determined from the rotational transitions in the ground torsional states, the only parameter that needs to be introduced is the one which describes the variation of the potential barrier height with respect to the vibrational coordinate. Hecht and Dennison[21] have been able to explain quantitatively some thirty splittings of lines of normal methyl alcohol and five other isotopes using only six empirical parameters.

This treatment can, in principle, be applied to determine the potential barrier of symmetric top molecules for which the methods described previously (PAM and IAM) fail. However, the force constants for most of the symmetric top molecules are usually not known to a sufficient degree of accuracy and therefore it becomes necessary to introduce several empirically determined parameters. A reliable result on the barrier height is obtained only if a sufficiently large number of lines in the excited torsional levels can be observed.

Recently, Swan and Strandberg[103] reanalyzed the results on methyl alcohol considering vibration rotation interaction more completely. By using the observed

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

infrared vibrational spectrum for the normal frequencies they diagonalized the vibration-rotation-internal rotation matrix, i.e., they attempted to calculate the empirical constants F_v, G_v, etc., from the vibrational wave functions. As Hecht and Dennison point out, this procedure can, at present, only be used to verify constants but not calculate good values for them. This is borne out in Swan and Strandberg's results in which the quantitative fit of the calculated frequencies to the observed is only fair. Nevertheless, this type of calculation is valuable, and with improved wave function and energy values a better quantitative agreement on molecules might be obtainable.

II. Intensity Method

The ratio of the intensity (I_1/I_0) of given rotational transitions in the first excited torsional state to the ground torsional state is equal to the relative population in the two torsional states, i.e.,

$$I_1/I_0 = (g_1/g_0)e^{\Delta E_v/kT}, \qquad (7\text{-}9)$$

where g_0 and g_1 are the statistical weights of the ground and the excited torsional states and ΔE_v is the difference in energy between these two states. Since the ratio of g_1 and g_0 can be determined from group-theoretical consideration, a measurement of the relative intensities between a rotational line and its satellite gives the torsional frequency which, with the aid of the Mathieu tables,[36,104] leads to a determination of the potential barrier. Where there are uncertainties as to the ratio of the statistical weights of the two levels, the relative intensity can be measured at several different temperatures.

One of the first molecules studied by this technique was CH_3CF_3.[14,72] The barrier heights of a number of other molecules obtained by this procedure are summarized in Table X. The main virtue of the intensity method lies on its simplicity and its applicability to the case of very high barrier in which the splitting between the A and E lines are undetectably small. However, the experimental error involved in the relative intensity measurement is rather large—usually 10 to 20% or even higher. It is therefore not surprising that some of the resulting barrier heights obtained represent little more than estimates.

Baird and Bird[2] studied the problem of the measurement of relative intensities in the microwave region. They propose a procedure by which one can obtain an improvement in accuracy and reproducibility of the intensity ratio. Unfortunately, their technique or one comparable has generally not been used in the work reported in Table X. Recently, Verdier and Wilson[111] obtained more refined measurement on the relative intensities for the spectral lines of CH_3CHO and CH_3CH_2F using a Stark-modulated cavity. Their results on the barrier height compare favorably with those obtained by the "splitting methods" (see Table IX). They point out some limitations of the intensity method.

First, the quantity measured is usually the ratio of the peak absorption heights. The absorption coefficient of a line at its center for a Van Vleck-Weisskopf line shape is given in Eq. (7-10)[108]:

$$\alpha(\nu_0) = (16\pi^3 n_0 |\mu_{mn}|^2 \nu_0 \tau)/3kcT, \qquad (7\text{-}10)$$

where n_0 is the number of molecules per unit volume in the lower level of the transition, μ_{mn} is the matrix element of the dipole moment between the upper and the lower level, and τ is the mean interval between collisions. In order to compare the peak absorption coefficients of two lines ν_0, μ_{mn}, τ, and T must be the same, otherwise any difference will contribute to a correction term in the intensity ratio. The temperature T will undoubtedly be the same for the two lines. The correction for the difference in ν_0 can be made easily. However, the two are usually so nearly equal that this correction is negligible. The transition moment μ_{mn} may be different, because the asymmetry parameter could change from the ground to the excited state. For certain transitions in nearly symmetric tops, μ_{mn} may be quite sensitive to a small change in the asymmetry parameter and in such case an appropriate correction in Eq. (7-10) should be applied. The variation in τ between torsional levels should normally be within the limit of experimental accuracy.

The second difficulty which might arise is that the A and E lines are not resolved, and yet the separation between these lines is about the same order of magnitude as the line width; the measured peak intensity then does not correspond to Eq. (7-10). For example, it may happen that the A and E lines are resolved in the excited torsional state but overlap (with only one peak) in the ground state. In this case serious error would result if a correction were not applied to the measured intensity ratio. In order to correct for this effect, one can measure the integrated intensity of these lines instead of the peak value. The integrated intensity of the resolved A or E line is then one-half of that of the composite line. Alternatively, if the splitting of the unresolved doublet is calculated from theory, then a relation between the actual and apparent peak absorption can be derived by adding two Van Vleck-Weisskopf shaped lines separated by a frequency equal to the splitting of the doublet.

8. EXPERIMENTAL RESULTS

Table IX gives the experimental values for the barrier heights determined from frequency measurements of the microwave spectra. If more than one value is available in the literature, the best value according to our opinion is reported.§§§§§

§§§§§ The major references on each molecule are listed and the one which gave the best value for the barrier as shown in Table IX is underlined.

As discussed in Secs. 3, 4, and 5, the ratio V_3/F is determined from the analysis of a microwave spectrum. In general, this ratio can be determined to an accuracy of two percent or better. Uncertainties in the molecular structure and limitations in the approximations are the two main sources of error. The spectra of molecules with lower s values are influenced to a much larger extent by the internal rotation and usually these can be analyzed to give somewhat more accurate values for the ratio V_3/F. Structural errors, in regard to the reduced moment of inertia of the methyl group, cause a large share of the error in the barrier. In our opinion, the barrier heights reported in Table IX are accurate to somewhere between 2% and 5%.

The spectra of methyl alcohol and methyl amine have been studied very thoroughly in the microwave region. Furthermore, a considerable amount of work has been done on their theoretical interpretation using

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the IAM given in Sec. 3. To a lesser extent methyl mercaptan has also been studied. These three molecules are of the class of an intermediate barrier molecule with slight asymmetry. Mainly the perpendicular ($\Delta K = \pm 1$) Q branch lines ($\Delta J = 0$) have been analyzed for the barrier height. The effects of the asymmetry and the off-diagonal internal rotational matrix elements are calculated by second-order perturbation. Methyl amine has the additional complication of inversion similar to ammonia.

Also the $J = 1 \leftarrow 0$, $K = 0$ transition has been analyzed for methyl alcohol[21,77,103] including the effects of nonrigidity. The splittings of the internal rotation doublets are caused by the rigid internal torsion as well as the molecular vibration, but the division between these two effects is not known accurately since it depends rather critically on the structure of the molecule. Slight shifts in the methyl group axis affect this division. With six empirical constants a good agreement between the theory and experiment was obtained for the frequency shifts of the excited states transitions for a number of isotopes of methyl alcohol. Nishikawa[77] obtained a good fit of the spectrum with only the three symmetric top constants. Attempts have been made[103] to calculate these "empirical constants" from the vibrational wave functions and qualitative agreement between the calculated and observed values has been obtained.

The results of the barrier height of methyl alcohol and methyl amine obtained by various methods are all in good agreement. However, for methyl mercaptan the situation is somewhat confusing. Intensity work by Solimene and Dailey[95] gave a value of 371 cm^{-1}. Kilb[35] determined a value of 246 cm^{-1} by rigid hindered theory (PAM to second order) on the $J = 1 \leftarrow 0$ transitions of a large number of isotopic species measured by Solimene and Dailey.[95] Kojima and Nishikawa first obtained a barrier[49] of 280 cm^{-1}, but subsequently they revised their value[50] to 444 cm^{-1}. Also the $J = 1 \leftarrow 0$ lines of the isotopic species $C^{12}H_3SH$, $C^{13}H_3SH$, $C^{12}D_3SH$, and $C^{12}H_3SD$ were analyzed by the symmetric top nonrigidity theory. According to Kojima and Nishikawa the $J = 1 \leftarrow 0$ of $C^{12}H_3SD$ was incorrectly assigned by Solimene and Dailey. The results of Kojima and Nishikawa[50] are probably more accurate because their analysis was carried out to a higher order of approximation.

The molecules acetaldehyde (CH_3CHO), acetyl fluoride (CH_3COF), acetyl chloride (CH_3COCl), acetyl cyanide (CH_3COCN), propylene ($CH_3CH=CH_2$), 1 fluoropropene ($CH_3CH=CHF$), methyl allene ($CH_3CH=C=CH_2$), methyl silane (CH_3SiH_3), methyl fluorosilane (CH_3SiFH_2), and methyl difluorosilane (CH_3SiF_2H) are examples of molecules with relatively high barriers. A pseudo-rigid rotor splitting was used to determine the barrier height. In some cases transitions up to $J = 12$ were analyzed using the PAM. Also in the near symmetric top molecules the first-order (nonrigid rotor) terms produced a large effect. This was especially true in acetaldehyde[38] (see Sec. 5) and methyl silane, mono-, and di-deuterated.[39] Methyl silane has been analyzed by nonrigidity theory[42] and all of the determined barrier heights agree very well with one another.

The barrier heights in ethyl fluoride,[22] 1,1-difluoroethane,[22] ethyl chloride,[66a] and ethyl bromide[66a] were determined by the splittings in the first excited torsional state since the ground state splittings were too small to observe. To a good approximation the splittings of the satellites of the first excited torsional state are caused entirely by the hindered rotation (but not the molecular vibrations) because of the high barrier.

In propylene oxide[27] the barrier was determined by the splittings in the ground and first two excited torsional states. The agreement is exceedingly good indicating the validity of using excited state splittings for the determination of barrier heights in molecules of high barriers. No effects of a V_6 potential were observed.

Acetic acid[105] is a molecule with an intermediate barrier and large asymmetry. Unusual difficulty was encountered in the analysis, but, by using the PAM to fourth order, Tabor was able to assign a number of higher J lines. The assignment was one of the more difficult aspects of this problem. The IAM would have been very difficult to use in this particular case because of the relatively high J transitions necessary for its analysis.

Low barriers have been observed in nitromethane and methyl boron difluoride. Here the $m = 3$ lines give an accurate determination of the barrier height. In the low barrier problem the initial assignment is quite difficult and an extensive searching of the lines is needed. The accuracy of these barrier heights is exceedingly good and generally better than that in the high barrier case. This results from the wide splittings of the order of 1000 Mc as compared with small splittings of a few Mc of the high barrier problems. The very low barrier obtained in these two cases for a sixfold potential seem to indicate that the ratio of V_3 to V_6 is generally of the order of 100. 1-chloro butyne-2 is another molecule with a low barrier which has been recently studied.[53b] Only an upper limit of the barrier height has been obtained.

The barriers have been determined for a number of molecules by the intensity method of Sec. 7. These are listed in Table X. Generally, an error of 10 to 20% can by assigned to these determined barrier heights. It is interesting to compare some of the results in Table X with the more accurate values of Table IX. Ethyl bromide[115,116] is 21% low; ethyl chloride[112,114], 4.5% low; ethyl fluoride[111] is in agreement; and 1,1-difluoroethane[94] is 12% high. By taking into account a 5% error in the values in Table IX, we can see that 10–20% error in the values of Table X is quite realistic.

It is interesting to compare the results of the barrier heights obtained by microwave spectroscopy with those from other means, particularly the thermodynamic methods (see Sec. 1). While detailed examinations of

the thermodynamic results are beyond the scope of this paper, it may be stated that the barrier heights determined by the splitting methods are usually more accurate than those obtained from the thermodynamic properties of the molecules. On the other hand, the intensity and thermodynamical methods yield results of comparable accuracy (ten to twenty percent uncertainty). With careful experimental measurements and in favorable cases, this error may be somewhat lower for both of these methods. In the absence of any frequency work on a given molecule, a careful investigation of the specific experimental difficulties is required in order to decide whether the thermodynamic results or the microwave intensity results are more reliable.

In addition to the barrier heights, the equilibrium configuration has been obtained for a number of molecules listed in Table XI. These equilibrium configurations are valuable because they supply additional information which, besides the barrier heights, any theory of the origin of barriers must explain. Ethyl chloride monodeuterated[113] was the first molecule in which the staggered configuration was confirmed by microwave spectroscopy. The tunneling rate is much slower than the measurement time in the microwave region so the two different configurations are observed: the deuterium gauche and trans to the chlorine atom. Each of these was observed. Even with only an approximate structure these observed rotational constants would be inconsistent with an eclipsed configuration.

Finally, a few molecules have been studied recently with two internal rotors. Although the theory, an extension of the work of Sec. 3, is not covered here [see references 84, 40, 100, and 33(b)], the results on acetone, dimethyl ether, and dimethyl silane are given in Table IX. The theory of internal rotation for molecules with an asymmetric internal rotor is not covered in this review, but two molecules, hydrogen peroxide,[70] and phenol,[50b] have been studied and analyzed approximately as a symmetric top. References 6, 9, and 86 give some of the theoretical work.

TABLE XI. Equilibrium configuration.

Compound	Formula	Configuration	Reference
Acetaldehyde	CH_2DCHO CHD_2CHO	Methyl group eclipses O and staggers H	38
Acetyl chloride	CH_2DCOCl CHD_2COCl	Methyl group eclipses O and staggers Cl	93
Acetyl cyanide	CH_2DCOCN CHD_2COCN	Methyl group eclipses O and staggers CN	52
Acetal fluoride	CH_2DCOF CHD_2COF	Methyl group eclipses O and staggers F	80
Propylene	$CH_2DCH=CH_2$	Methyl group eclipses the double bond and staggers H	26
Ethyl chloride	CH_2D-CH_2Cl	staggered	113
Methyl silane	CH_2D-SiH_2D $CH_2D-SiHD_2$	staggered	39
Methyl fluorosilane	CH_2D-SiH_2F	staggered	81a
1,1-Difluorosilane	CH_2DSiHF_2 CHD_2SiHF_2	staggered	25c

9. CONCLUSIONS

After the various discussions on the interactions of internal rotation and over-all rotation, one naturally questions what causes these potential barriers and whether the values reported in Sec. 8 can be explained quantitatively in terms of the electronic structure of the molecules. Furthermore, can unknown barrier heights be predicted satisfactorily? Numerous attempts have been made (see Bibliography—Theoretical and Empirical Methods of Barrier Height Estimation) to provide answers to these questions, but the results do not seem very encouraging. This is understandable since the potential barrier represents only a very small fraction of the binding energy of the molecule. It seems highly impractical at this time to make any serious attempt to evaluate the barrier heights by the direct

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and rigorous approach, i.e., from the difference in energy of the entire molecule for the two extreme configurations corresponding to the eclipsed form ($\alpha=60°$) and the staggered form ($\alpha=0°$).

In order to offer a simple picture for the nature of the hindering potential, various mechanisms such as Van der Waals forces,[012,016] direct electrostatic interactions,[03,010,013] overlap, and exchange force,[014] have been proposed for the intramolecular interaction. Recently, Wilson[017,018] has made a critical examination of these various hypotheses and found that none of the existing theories can account for the experimental results of the barrier heights of the various molecules. He [017] suggests that the potential barrier could be an inherent property of the axial bond itself and that it is is not due to the direct forces between the attached atoms to any great extent or to the electronic distribution in the attached bonds which are at any considerable distance. Pauling,[014] on the other hand, hypothesizes that exchange interactions of the electrons in the attached bonds, as determined by the overlap of these attached bonds which extend in the direction of the axial bond toward one another, are responsible for the potential barrier. By the use of higher orbitals, d and f, he makes a rough estimate of this nonbonding interaction which is in the right order of magnitude for the observed potential barriers. Although the absolute values are only fortuitous, a number of interesting relative values are presented. From his hypothesis, unshared electron pairs, which do not hybridize with the f orbitals, would not contribute to the potential barrier, i.e., methyl alcohol would have a barrier approximately one-third of that in ethane and methyl amine would have a barrier approximately two-thirds of that of ethane. Another interesting point is the existence of the very low barriers in molecules such as nitromethane. A sixfold barrier would require i orbitals with an azimuthal quantum number $l=6$. Because of the large promotional energy these probably would not contribute much to the hybrid bond orbitals and hence we would predict a low barrier.

Which of these various mechanisms, or combination of mechanisms, correctly accounts for the potential barriers measured in molecules is still unanswered. It is hoped that this review will stimulate further research toward the understanding of the origin of the potential energy hindering internal rotation. Nevertheless, from the viewpoint of molecular dynamics, the problem of internal rotation in molecules, i.e., the effect of the internal rotation on the energy levels, is quite well understood. The agreement between the theory and the observed spectra, including all the fine details, is particularly outstanding. Furthermore, the study of the microwave spectra offers a method, which is by far the most accurate at the present time, for determining the height and the shape of the hindering barrier.

APPENDIX 1

Derivation of Kinetic Energy and Angular Momentum

In Fig. 9, O and C represent, respectively, the center of mass of the entire molecule and of the top alone. Two vectors $\mathbf{r}_j$ and $\boldsymbol{\sigma}_j$ are drawn to a typical atom in the top from the respective centers of mass O and C. The position vector (with O as origin) for an atom in the framework will be denoted by $\mathbf{r}_i$. If $\boldsymbol{\varrho}$ denotes the vector from O to C, one can readily see that

$$\mathbf{r}_j=\boldsymbol{\varrho}+\boldsymbol{\sigma}_j. \tag{A1-1}$$

The kinetic energy can be written as

$$T=\tfrac{1}{2}\sum_i m_i(\partial\mathbf{r}_i/\partial t)\cdot(\partial\mathbf{r}_i/\partial t) +\tfrac{1}{2}\sum_j m_j(\partial\mathbf{r}_j/\partial t)\cdot(\partial\mathbf{r}_j/\partial t). \tag{A1-2}$$

By remembering that

$$(\partial\mathbf{r}_i/\partial t)=\boldsymbol{\omega}\times\mathbf{r}_i,\quad (\partial\mathbf{r}_j/\partial t)=\boldsymbol{\omega}\times\mathbf{r}_j+(\partial\boldsymbol{\alpha}/\partial t)\times\boldsymbol{\sigma}_j,$$

where ω is the angular velocity of the over-all rotation of the molecule, one can rewrite (A1-2) in the form of

$$\begin{aligned}T&=\tfrac{1}{2}\sum_i m_i(\boldsymbol{\omega}\times\mathbf{r}_i)^2+\tfrac{1}{2}\sum_j m_j[(\boldsymbol{\omega}\times\mathbf{r}_j)+(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)]^2\\ &=\tfrac{1}{2}\sum_i m_i[r_i^2\omega^2-(\boldsymbol{\omega}\cdot\mathbf{r}_i)^2]+\tfrac{1}{2}\sum_j m_j[r_j^2\omega^2-(\boldsymbol{\omega}\cdot\mathbf{r}_j)^2]\\ &\quad+\tfrac{1}{2}\sum_j m_j[\sigma_j^2\dot{\alpha}^2-(\boldsymbol{\sigma}_j\cdot\partial\boldsymbol{\alpha}/\partial t)^2]\\ &\quad+\sum_j m_j(\boldsymbol{\omega}\times\mathbf{r}_j)\cdot(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j).\end{aligned} \tag{A1-3}$$

The first two terms obviously represent the kinetic energy of the over-all rigid rotation of the molecule with angular velocity $\boldsymbol{\omega}$, and can be written as $\frac{1}{2}\boldsymbol{\omega}^+\cdot\mathbf{I}\cdot\boldsymbol{\omega}$ where $\mathbf{I}$ is the usual inertia tensor of the entire molecule. The third term may be expressed as $\frac{1}{2}I_\alpha\dot{\alpha}^2$ where I_α is the moment of inertia of the top about its own axis of symmetry. The last term may be simplified as

$$\begin{aligned}&\sum_j m_j(\boldsymbol{\omega}\times\mathbf{r}_j)\cdot(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)\\ &=\sum_j m_j\{[(\boldsymbol{\varrho}+\boldsymbol{\sigma}_j)\cdot\boldsymbol{\sigma}_j](\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t)\\ &-(\boldsymbol{\omega}\cdot\boldsymbol{\sigma}_j)[(\boldsymbol{\varrho}+\boldsymbol{\sigma}_j)(\partial\boldsymbol{\alpha}/\partial t)]\}\\ &=\sum_j m_j[\sigma_j^2(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t)-(\boldsymbol{\omega}\cdot\boldsymbol{\sigma}_j)(\boldsymbol{\sigma}_j\cdot\partial\boldsymbol{\alpha}/\partial t)].\end{aligned} \tag{A1-4}$$

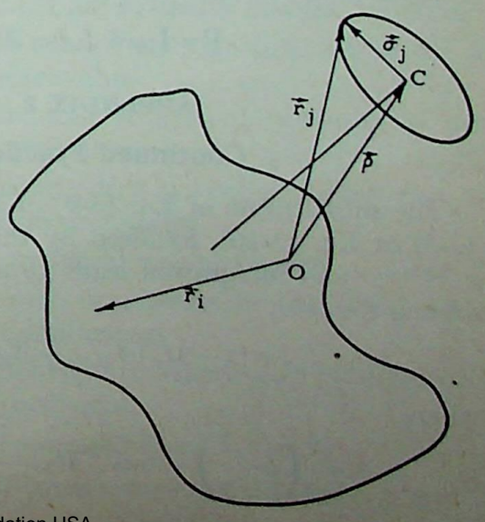

FIG. 9. The position vectors of typical atoms in a molecule with an attached internal rotor. The O position and C position represent the centers of mass of the whole molecule and the internal rotor, respectively. The vectors $\mathbf{r}_i$ and $\mathbf{r}_j$ are vectors from the center of mass O to typical atoms in the frame of the molecule and the internal rotor.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The last step follows from the relation

$$\sum_j m_j \boldsymbol{\sigma}_j = 0.$$

By using a coordinate system attached to the top with the z axis along the axis of symmetry, and the origin located at the center of mass of the top, one has

$$\boldsymbol{\sigma}_j = x_j\hat{\imath} + y_j\hat{\jmath} + z_j\hat{k},$$

and

$$\sum_j m_j x_j z_j = \sum_j m_j y_j z_j = 0.$$

Equation (A1-4) then takes the form of

$$\begin{aligned}&\sum_j m_j[(x_j^2+y_j^2+z_j^2)(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t)\\&\quad-(\omega_x x_j+\omega_y y_j+\omega_z z_j)z_j|\partial\boldsymbol{\alpha}/\partial t|]\\&=\sum_j m_j[(x_j^2+y_j^2+z_j^2)(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t)-\omega_z z_j^2|\partial\boldsymbol{\alpha}/\partial t|]\\&=\sum_j m_j(x_j^2+y_j^2)(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t)=I_\alpha(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t).\end{aligned}$$

The kinetic energy finally becomes

$$T=\tfrac{1}{2}\boldsymbol{\omega}^+\cdot\mathbf{I}\cdot\boldsymbol{\omega}+\tfrac{1}{2}I_\alpha\dot{\alpha}^2+I_\alpha(\boldsymbol{\omega}\cdot\partial\boldsymbol{\alpha}/\partial t). \quad \text{(A1-5)}$$

The classical angular momentum is given by

$$\begin{aligned}\mathbf{P}&=\sum_i m_i(\mathbf{r}_i\times\partial\mathbf{r}_i/\partial t)+\sum_j m_j(\mathbf{r}_j\times\partial\mathbf{r}_j/\partial t)\\&=\sum_i m_i[\mathbf{r}_i\times(\boldsymbol{\omega}\times\mathbf{r}_i)]\\&\quad+\sum_j m_j[\mathbf{r}_j\times\{(\boldsymbol{\omega}\times\mathbf{r}_j)+(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)\}]\\&=\sum_i m_i[\mathbf{r}_i\times(\boldsymbol{\omega}\times\mathbf{r}_i)]+\sum_j m_j[\mathbf{r}_j\times(\boldsymbol{\omega}\times\mathbf{r}_j)]\\&\quad+\sum_j m_j[\mathbf{r}_j\times(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)]. \quad \text{(A1-6)}\end{aligned}$$

The first two terms stand for the angular momentum of the over-all rigid rotation of the entire molecule which can be written as $\mathbf{I}\cdot\boldsymbol{\omega}$. In order to simplify the last term, use is made of the fact that $\boldsymbol{\sigma}_j$ is a vector measured from the center of mass of the top and that the axis of the top is a principal axis of the top. It follows that

$$\begin{aligned}&\sum m_j[\mathbf{r}_j\times(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)]\\&\quad=\sum m_j[(\boldsymbol{\varrho}+\boldsymbol{\sigma}_j)\times(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)]\\&\quad=\sum m_j[\boldsymbol{\sigma}_j\times(\partial\boldsymbol{\alpha}/\partial t\times\boldsymbol{\sigma}_j)]\\&\quad=\sum m_j[\sigma_j^2\partial\boldsymbol{\alpha}/\partial t-(\boldsymbol{\sigma}_j\cdot\partial\boldsymbol{\alpha}/\partial t)\boldsymbol{\sigma}_j]\\&\quad=\sum m_j[\sigma_j^2\hat{k}|\partial\boldsymbol{\alpha}/\partial t|-z_j^2\hat{k}|\partial\boldsymbol{\alpha}/\partial t|]=I_\alpha\partial\boldsymbol{\alpha}/\partial t.\end{aligned}$$

Equation (A1-6) then reduces to

$$\mathbf{P}=\mathbf{I}\cdot\boldsymbol{\omega}+I_\alpha\partial\boldsymbol{\alpha}/\partial t.$$

APPENDIX 2

Continued Fraction

The substitution of Eq. (3-9) or Eq. (3-23) into Eq. (3-3) or Eq. (3-16), followed by the multiplication by $e^{-i(3k+\sigma)\alpha}$ and integration leads to a recursion formula among the A's:

$$A_{3(k-1)+\sigma}+(\lambda-M_k)A_{3k+\sigma}+A_{3(k+1)+\sigma}=0, \quad \text{(A2-1)}$$

where

$$\lambda=\frac{4}{s}\left(b-\frac{s}{2}\right) \quad \text{and} \quad M_k=\frac{16}{9s}(3k+\sigma)^2.$$

This defines an infinite set of homogeneous equations. In order to have a nontrivial solution it is necessary that the determinant of the coefficients vanish. This infinite determinant can be factored into 3 different subdeterminants, one for each σ value. Koehler and Dennison[48] have shown that Eq. (A2-1) leads to a continued fraction. This can easily be seen by dividing the recursion relation Eq. (A2-1) by $A_{3k+\sigma}$:

$$\frac{A_{3(k+1)+\sigma}}{A_{3k+\sigma}}=(M_k-\lambda)-\frac{A_{3(k-1)+\sigma}}{A_{3k+\sigma}}, \quad \text{(A2-2)}$$

and inverting

$$\frac{A_{3k+\sigma}}{A_{3(k+1)+\sigma}}=\frac{1}{M_k-\lambda-\dfrac{A_{3(k-1)+\sigma}}{A_{3k+\sigma}}}=\frac{1}{M_k-\lambda-\dfrac{1}{M_{k-1}-\lambda-\cdots}}=G_k^-,$$

also

$$\frac{A_{3k+\sigma}}{A_{3(k-1)+\sigma}}=\frac{1}{M_k-\lambda-\dfrac{1}{M_{k+1}-\lambda-\cdots}}=G_k^+.$$

By substituting back into Eq. (A2-1), one obtains a continued fraction equation,

$$\lambda=M_k-G_{k+1}^+-G_{k-1}^-. \quad \text{(A2-3)}$$

A trial value of λ is substituted into G^+ and G^- leading to a first approximation of λ. By successive iteration a consistent value of the eigenvalue, λ, is obtained. The continued fraction does not always converge very rapidly and can even diverge. The use of a Newton Raphson approximation[69] is recommended to avoid this difficulty. By letting

$$f(\lambda)=M_k-\lambda-G_{k+1}^+(\lambda)-G_{k-1}^-(\lambda)=0,$$

and expanding at the nth approximation of the eigenvalue (denoted by λ^n), one obtains

$$\begin{aligned}f(\lambda)&=f(\lambda^n)+(\lambda-\lambda^n)f'(\lambda^n)\\&=\lambda^{n+1}-\lambda^n+(\lambda-\lambda^n)f'(\lambda^n)=0.\end{aligned}$$

Then

$$\lambda=\lambda^n+\frac{\lambda^{n+1}-\lambda^n}{-f'(\lambda^n)}, \quad \text{(A2-4)}$$

where

$$\begin{aligned}-f'(\lambda^n)&=1+G_{k+1}^{+2}[1+G_{k+2}^{+2}(1+\cdots)]\\&\quad+G_{k-1}^{-2}[1+G_{k-2}^{-2}(1+\cdots)].\end{aligned}$$

Since the G's are determined in the calculation of the eigenvalue, the derivative $f'(\lambda^n)$ is readily calculated. Care must also be taken to insure that the initial approximation is not separated from the desired eigenvalue by a pole. A pole occurs between each eigen-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

value. If one exists between the first approximation and the desired root, the continued fraction converges to the adjacent root.

With the desired eigenvalue determined, a substitution into Eq. (A2-1) leads to a recursion relation between the A's. By solving these relations and normalizing, one obtains the eigenfunctions. These eigenfunctions are used to determine the matrix elements and integrals for the IAM and PAM if the approximations given are not sufficiently accurate. The eigenfunctions are tabulated for the periodic solutions.[104,37] For the nonperiodic solutions σ is replaced by $\sigma+\rho K$ in all the previous expressions.

APPENDIX 3

Tabulations Related to Mathieu Equations

The most recent and complete tabulations are listed in Table XII. References 36 and 104 are the most useful and complete for the threefold potential case. Also, by the use of Eq. (3-29) and these tables, the eigenvalues for $s>30$ for other periodicities can readily be determined. A number of older references are given in reference 104.

TABLE XII. Mathieu function tabulations.

Reference	Period in x	Range in V	Range in s	Accuracy
Mathieu Functions[a,c]	π, 2π	0(1)8 9(1)14	0(1)100[b] 0(2)100	1×10^{-8}
Kilb[c,d,e]	3π	0(1)5	2(1)30(2)52(4)100	1×10^{-10}
Stejskal[f]	π,3π	0(1)4	100(15)205	1×10^{-7}

Pexton[i]	4π	0(1)9	1(1)40	1×10^{-6}

[a] See reference 104.
[b] A close tabulation is given for the low s values.
[c] Eigenfunctions are also tabulated.
[d] Copies are available from E. B. Wilson, Jr., Department of Chemistry, Harvard University. Herschbach's tables are also available.
[e] See reference 36.
[f] See reference 96.
[g] See reference 5.
[h] Tabulated in terms of t 0(0.002)0.1 where $s=1/t^2$.
[i] Tabulated in Li and Pitzer reference 55. Notation: $4\theta=s$, $\theta_0=b-\frac{1}{2}s$.

Recently, Herschbach[23] tabulated the matrix elements p, p^2, p^3, cos6α, the perturbation sums to fourth order for use in the PAM, and the Fourier coefficients for use in the IAM.[25b] Herschbach gives a complete introduction explaining the use of the tables to solve the internal rotation problem. These tables are of great assistance in the computation for barrier problems.

APPENDIX 4

Notation

a	IAM "a" coordinate axis
a, a_K	expansion coefficients
a, a'	low barrier diagonal elements $\lvert m\rvert=3$
a_k	Fourier coefficient in potential energy
a_n	Fourier coefficient in IAM internal energy
amu	atomic mass units
A	symmetry species in C_3 group
A, A_a, $A_{v\sigma}$, A_x	rotational constants
$A_{3k+\sigma}{}^{v}$, $A_{3k+\sigma}{}^{Kv}$	wave function expansion coefficients
A	Angstrom unit
b	IAM "b" coordinate axis
b	expansion coefficients
b	low barrier off-diagonal element $\lvert m\rvert=3$
b, be, bo, b_i, $b(N\pi)$	Mathieu eigenvalues
B, B_b, $B_{v\sigma}$, B_y	rotational constants
B_e	equilibrium rotational constants
B, B_x, B_y, B_z	symmetry species
c	IAM "c" coordinate axis
c_k	Fourier coefficient of Mathieu's function
C, C_c, $C_{v\sigma}$, C_z	rotational constants
C_2, C_3, C_6, C_x	rotational symmetry operations
d	reducing factor, r, times $(I_xI_yI_z)$
d_k	Fourier coefficient of Mathieu's function
d_{XY}	interatomic distance from atom X to atom Y
D_{bc}, D_{ij}	Hamiltonian cross terms between components of the total angular momentum
De, Do	Fourier coefficients of Mathieu's function
$D^J(\beta)_{KpK}$	rotational transformation matrix element
E	symmetry species, degenerate
E	energy
$E(\kappa)$	reduced rigid rotor energy
E_{JKM}	rotational energy
$E_{v\sigma}$, $E_{Kv\sigma}$	torsional energy: PAM and IAM
$E(JKMv\sigma)$	total energy: rotation and torsion
f	Mathieu parameter (Floquet's theorem)
$f(x)$	IAM approximate integral function
$f(\lambda)$	continued fraction function of the λ eigenvalue
F	reduced rotational constant of the internal rotor
F_v	nonrigidity potential energy expansion coefficient
g_0, g_1	statistical weight factors
g^+, g^-	correction terms in the PAM rotational energy
G_v	nonrigidity kinetic energy expansion coefficient
$G_k{}^+$, $G_k{}^-$	continued fraction terms
$\hbar$	Planck's constant divided by 2π

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

H, H_0	Hamiltonian
H_{IR}	coupling term in Hamiltonian
H_R	rotational Hamiltonian
H_T	torsional Hamiltonian
H_v	vibration Hamiltonian, harmonic oscillator function
H_1	asymmetry term in Hamiltonian
$H_{v\sigma}$	rotational Hamiltonian for the $v\sigma$ torsion state
$\hat{\imath}$	unit vector
$\mathbf{I}$	moment of inertia tensor
$I_a, I_b, I_c, I_{aa}, I_{bb}$ $I_{cc}, I_g, I_x, I_y, I_z, I_{jk}$	moments of inertia
I_α	moment of inertia of the internal rotor about its symmetry axis
I_{bc}, I_{jk}	products of inertia
$\hat{\jmath}$	unit vector
J	quantum number of the total angular momentum
k	Boltzmann's constant
$\hat{k}$	unit vector
k^+, k^-	correction terms in the PAM rotational energy
K	quantum number of the total angular momentum along the molecular z axis
l	free rotation quantum number
L_v	nonrigidity angular momentum expansion coefficient
m	free rotation quantum number
m_i	mass of the ith atom
M	quantum number of the total angular momentum along the space axis
$M_{Kv\sigma}(\alpha)$	IAM nonperiodic torsional function
$M(x)$	Mathieu function
Mc	megacycles/second
M_k	continued fraction term
N	periodicity of the hindering potential
p	internal angular momentum
$p_{v\sigma,v'\sigma}$	PAM matrix element of the internal angular momentum
$P_g(P_a,P_b,P_c,P_j,P_k,P_x,P_y,P_z)$	the gth components of the angular momentum
P_g^{ij}	the gth component of the total angular momentum with the independent variables i and j constant
$P_{Kv\sigma}(\alpha)$	IAM torsional function for a symmetric molecule
Q_i	PAM Hamiltonian term
$Q_{Kv\sigma}(\alpha)$	IAM torsional function for an asymmetric molecule
r	reducing factor
$\mathbf{r}_i, \mathbf{r}_j$	position vector of the ith (j) atom
$r_a, r_b, r_c, r_x, r_y, r_z$	position vector components
s	reduced barrier height
S_1	rotational transformation matrix
S_2	asymmetric transformation matirx
Se, So	Mathieu functions
$S_{JKM}(\theta,\varphi)e^{iK\chi}$	symmetric rotor function
T	kinetic energy
T	temperature
$U_{v\sigma}(\alpha)$	PAM torsional function
v	torsional quantum number
$V(\alpha), V_N, V_3, V_6, V_{12}$	potential energy (subscript denotes periodicity)
$w_{v\sigma}^{(n)}$	PAM perturbation terms
W, W_r	rigid rotor energy
x	x principal axis
$x_{v\sigma}$	nonrigidity term
y	y principal axis
z	z principal axis
α	internal angle
α	direction cosine of ϱ to z principal axis
$\dot{\alpha}$	internal angular velocity
α_t, α_i	first term in the vibration rotation expansion of the rotational constant
β	direction cosine of ϱ to y principal axis
β_1, β_2	nonrigidity expansion terms
Δ_0	IAM splitting of internal sublevels for $K=0$
Δ_K	IAM splitting of internal sublevels for Kth level
ΔE_{JK}	internal rotational splitting of the J, K rotational level
$\Delta E(J_{K-1K+1})$	internal rotational splitting of the J_{K-1K+1} rotational level
δ_{Asy}	asymmetry splitting of K and $-K$ rotational levels
δ_K	nonrigid-rotor internal rotor splitting
$\delta_{K'v'\sigma}{}^{Kv\sigma}$	IAM integrals
δq_i	displacement coordinate
θ	Eulerian angle
κ	asymmetry parameter
λ	eigenvalue of a secular determinant
$\lambda_g, (\lambda_x,\lambda_y,\lambda_z)$	direction cosine of the internal rotor to the g principal axis
μ_{mn}	dipole matrix element
ν	frequency
Π	dot product of the total angular momentum vector and the vector $\mathbf{p}$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ϱ	(a) direction of the internal axis such that the internal angular momentum vanishes	σ_j	position vector of a top atom from the center of mass of the top (internal rotor)
	(b) position vector of the center of mass of the top from the center of mass of the whole molecule (Appendix 1)	τ	mean life time
		φ, Φ	Eulerian angles
		$\chi, \chi_1, \chi_2, \chi'$	Eulerian angles
		Ψ, ψ	wave function
		ω	total angular velocity vector
ρ_g	component of ϱ along the g axis	ω_g ($\omega_a, \omega_b, \omega_c, \omega_x, \omega_y, \omega_z$)	component of the total angular velocity along the g axis
σ	torsional sublevel quantum number

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the helpful comments and suggestions given by a large number of our friends and associates. We are particularly indebted to E. B. Wilson, Jr., D. R. Herschbach, R. W. Kilb, V. W. Laurie, L. C. Krisher, and T. N. Sarachman for their criticism and encouragement on this paper. We also wish to express our appreciation to D. G. Burkhard, A. E. Douglas, K. T. Hecht, H. E. Hoffman, T. Kojima, K. S. Pitzer, R. M. St. John, and M. W. P. Strandberg for many helpful discussions and correspondences concerning various parts of this review. Our thanks are also extended to Mrs. J. E. Locke, Mrs. V. S. Blohm, and particularly Mrs. Mary Swalen for typing the manuscript.

Foundations of the Optical Model for Nuclei and Direct Interaction

G. E. BROWN

Department of Mathematical Physics, University of Birmingham, Brimingham, England

I. INTRODUCTION

THIS paper gives a description of the scattering of particles of energies in the kev and Mev range by complex nuclei. Starting from exact many-level formulas for the scattering amplitude, we show that several phenomena which were inexplicable in the old compound-nucleus theory arise from phase relations between the nuclear levels, whereas terms in which phase relations would not seem to be important correspond to the scattering predicted by the old compound-nucleus picture, supplemented by statistical assumptions.

This paper might be described as a treatment of the theory of nuclear reactions in the region in which many nuclear levels participate in the scattering. Thus, it is complementary to the comprehensive article of Lane and Thomas[1] where the treatment is particularly appropriate to the case in which few levels contribute. These authors employed the R-matrix theory of Wigner and Eisenbud[2] which is especially well adapted to the low-energy case because it makes the energy dependence of all expressions as explicit as possible. We employ here the formalism of Kapur and Peierls[3] which has the great advantage for the many-level case that the sum over levels enters linearly into the scattering amplitude. The formalism employed is only an intermediate step to the final results, and, therefore, we choose the one that seems simplest for the particular development here.

Surveying first the old compound-nucleus picture, we note the points at which it must be revised. It was realized long ago that this was not a complete description; in fact N. Bohr[4] already suggested in 1938 that a particle, upon entering the nucleus, might go directly to a final state without forming a compound nucleus. However, most calculations were carried out with the extreme form of the model, and most physical pictures tended to follow in this way. By extreme form we mean the form in which it is assumed that the phases of contributions from different compound levels are random, and that they therefore do not interfere. Such assumptions are generally implicit in statistical calculations.

The compound-nucleus picture formulated by N. Bohr[5] explained the very narrow resonances observed in the elastic scattering of slow neutrons by assuming that the incident neutron, once inside the nucleus, shares its energy with many other nucleons through its strong interaction with them; the resulting compound nucleus then lasts a long time, until one of the nucleons acquires sufficient energy to escape from the nucleus. Because of the long lifetime of the state, the uncertainty principle shows that its energy can be well determined, and hence, that its width is small. The observed resonances were of the order of electron volts wide, about a million times narrower than the single-particle levels formed in the scattering of particles by the potential wells earlier assumed to represent the nucleus.

Since the observed compound-nucleus resonances were so long-lived, it was usually assumed that their characteristics are independent of the way in which they are formed, aside from restrictions resulting from conservation laws, and are also independent of the neighboring states. It seemed natural then to introduce statistical assumptions which neglected interference between the scattering from different levels. Then, in the neighborhood of a compound state, one could write the cross section $\sigma_{\alpha\beta,j}$ for a particle incident in "channel" α to emerge in "channel" β (we give precise definitions of all terms later), leaving the residual nucleus in excited state j as a product of factors

$$\sigma_{\alpha\beta,j}=\frac{\pi}{k^2}(2l+1)\frac{\gamma_{p\alpha}\gamma_{p\beta j}}{(\epsilon_p-E)^2+\alpha_p^2/4},$$

where p labels the compound state, $\gamma_{p\alpha}$ is the partial width[6] for formation of it by a particle in channel α, $\gamma_{p\beta j}$ is the partial width for its decay, α_p is the total width of the state, and ϵ_p is the real part of its energy. This type of formula, valid in the region of a single isolated level, was given by Breit and Wigner[7] and bears their names. The above expression for σ as a product of factors implies the independence of the processes of formation and decay of the level both from each other and from the properties of other levels.

It is clear that the number of compound states per unit energy interval increases rapidly with the energy of the incident particle. Already at energies in the kev range, the density of levels observed in the scattering of slow neutrons by medium and heavy nuclei is $\sim 10^4$

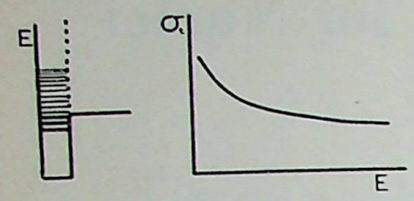

FIG. 1. The increasing density of nuclear levels with excitation energy is sketched on the left. Predictions of the continuum model for the behavior of the total cross section are shown on the right.

to 10^6 levels per Mev. Therefore, in the scattering of beams of neutrons which generally includes a spread in neutron energies of several Mev because of the experimental difficulty of producing monoenergetic neutrons of arbitrary energy, one might expect the cross section to approach that of a completely absorbing system with increasing neutron energy. A specific model incorporating these features was formulated by Feshbach, Peaslee, and Weisskopf[8] and is known as the continuum model. Here, the wave function of the neutron incident on the nucleus is subjected to the requirement that it have only an incoming part at the nuclear radius, i.e., that

$$d/dr[r\psi(r)]|_{r=R} = -iKR\psi(R),$$

where $\psi(r)$ is the wave function for the incident neutron, R is the nuclear radius, and K is an "internal" wave number that the neutron is supposed to possess inside the nucleus as a result of its interaction with the other nucleons. The predictions of such a theory for the total cross section are illustrated in Fig. 1 which also gives an indication of how the number of compound states increases with increasing excitation energy. The negative energy states of the nucleus are shown schematically as bound states in a potential well. At high energies the total cross section approaches $2\pi R^2$. The rise in the curve at lower energies is due to the fact that, in this model, the particle "feels" the nucleus already at distance $R+\lambda\!\!\!^{-}$, where $\lambda\!\!\!^{-}=\lambda/2\pi$ and λ is the wavelength, because of quantum-mechanical effects.

Contrary to expectations, the experimental cross sections, for beams in which the neutrons had a spread of energies, showed giant maxima of widths of the order of one or two Mev, as indicated schematically in Fig. 2. These were reproduced theoretically in the later theory of Feshbach, Porter, and Weisskopf[9] by the scattering from a complex potential well in which the real part represents some average interaction of the incoming nucleon with the nuclear particles, and the imaginary part, the disappearance of particles out of the incident

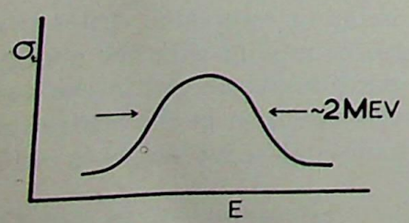

FIG. 2. Sketch of a giant resonance of the type observed in the scattering of neutrons by complex nuclei.

beam into compound states. There is no natural explanation for such giant resonances in the extreme compound-nucleus picture, and the representation of the nucleus by a complex well indicates a major modification.

Other phenomena which demanded modification of the extreme compound-nucleus picture were observed in the inelastic scattering of nucleons by complex nuclei. The predictions of the compound-nucleus model, supplemented by statistical assumptions, are shown as the solid line in Fig. 3. In this picture, the probability of leaving the nucleus in the various excited levels is assumed the same for all levels, aside from kinematical factors. The curve therefore rises as the energy taken off by the scattered particle decreases (and the energy left to the nucleus increases) and is cut off only when the wave number of the escaping nucleon (or nucleons) is so small that it will be reflected at the nuclear surface. Experimentally, an anomalously large number of fast particles was observed, as indicated by the dotted line in Fig. 3. Processes responsible for the high-energy particles were qualitatively well described by the direct interaction formalism of Austern, Butler, and

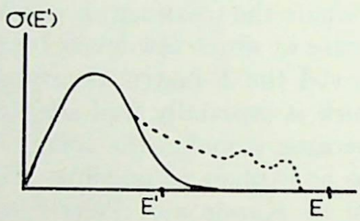

FIG. 3. The solid line shows typical predictions of the statistical model for the spectrum of inelastically-scattered neutrons. The energy of the emitted neutron is denoted by E'. The dashed line indicates the type of spectrum observed experimentally.

McManus.[10] Here, the incident particle is assumed to "chip" off particles from the nuclear surface without formation of a compound state. For example, the transition element for the nucleus to go from state i to state f is assumed to be

$$M_{if} = -\frac{2M}{\hbar^2}\int_{r_0}^{\infty} \chi_f(\xi) e^{-i\mathbf{k}_f\cdot\mathbf{r}} V(\mathbf{r}-\xi) e^{i\mathbf{k}_i\cdot\mathbf{r}} \chi_i(\xi) d^3\xi d^3r,$$

where $\exp i\mathbf{k}_i\cdot\mathbf{r}$ and $\exp i\mathbf{k}_f\cdot\mathbf{r}$ are the wave functions of the incident and scattered nucleon, and $\chi_0(\xi)$ and $\chi_f(\xi)$ those of the initial and residual nucleus. Here $\mathbf{r}$ represents the coordinate of the incident nucleon and ξ the totality of nuclear coordinates, conventions that are used throughout. The radius r_0 is supposed to define the point at which the "surface" begins and was chosen so as to fit the experimental angular distributions.

The form of this theory was suggested by the earlier description by Butler[11] of deuteron stripping which is also a form of "direct interaction." However, for sim-

plicity, we discuss the scattering of nucleons since complications are introduced by the composite structure of deuterons or α-particles.

Many experiments have shown that the high-energy particles in these inelastic processes have angular distributions, usually peaked towards small angles, whereas the low-energy nucleons have comparatively structureless, symmetrical angular distributions, as would be predicted by the statistical theory, and this is a further indication of the direct nature of the high-energy processes.

A further phenomenon which violates the early compound-nucleus picture occurs in the dipole photoeffect. Here, the absorption cross section for all complex nuclei shows a gaint maximum in the region of 15 Mev for heavy nuclei. This maximum was explained by Goldhaber and Teller[12] and Steinwedel and Jensen[13] in terms of a collective oscillation of proton density. However, the decay of such a system, in which the energy is almost evenly distributed over all particles, ought to be adequately represented by the statistical theory. In the case of medium and heavy nuclei, the number of high-energy protons observed is far in excess of that predicted by this theory, often by several orders of magnitude. Such high-energy protons are predicted naturally by Wilkinson's[14] picture of the giant dipole photoeffect, in which the γ-ray is absorbed by a nucleon which then goes into a single-particle state in a complex well, and consequently has an appreciable chance of escaping with the full energy of the γ-ray before being absorbed into compound states. (This absorption is again described through the imaginary part of the well.)

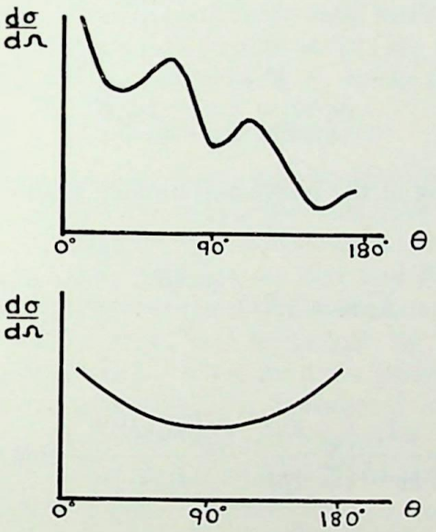

FIG. 4. In the upper figure, the angular distribution of the high-energy part of the inelastic spectrum, Fig. 3, is sketched; in the lower, that of the low-energy part of the spectrum.

Thus, although the old compound-nucleus picture had to be modified, the new phenomena could be reproduced by simple physical models which employed a complex well. However, conceptually, the description was not complete because it was known from cases where the cross sections could be investigated in detail that the giant resonances actually consist of thousands or millions of compound levels, and the relation between the detailed behavior—which often could not be investigated experimentally, but could be inferred—and the average behavior as predicted by the complex well had to be clarified. Further, the connection of the parameters of the optical well with more fundamental quantities such as the nucleon-nucleon force had to be made.

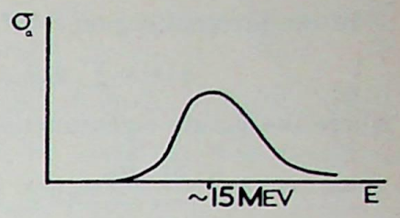

FIG. 5. The absorption cross section for γ-rays showing the giant dipole resonance.

A unified description of the above phenomena begins from an exact description in terms of nuclear dispersion theory. The scattering amplitude is separated into terms corresponding to direct interactions and compound-nucleus processes. Before going into such a description, however, we review the dispersion theory of Kapur and Peierls,[3] which is used in the later development, and present a simplified picture illustrating the physical assumptions employed later in the more formal arguments.

II. KAPUR-PEIERLS DISPERSION FORMALISM

1. Scattering by a Potential Well

We begin by treating the scattering of an S-wave neutron by a potential well; this simple example illustrates the main features of the theory. The Schrödinger equation for this case is

$$\frac{h^2}{2M}\frac{d^2\phi}{dr^2}+[E-V(r)]\phi=0, \tag{1}$$

where $V(r)$ is the potential and $\phi(r)=r\psi(r)$ with ψ the wave function of the neutron. For radii r greater than some radius R, beyond which the potential $V(r)$ is zero,

$$(d^2\phi/dr^2)+k^2\phi=0, \quad r>R, \tag{2}$$

with

$$k^2=2ME/\hbar^2. \tag{2.1}$$

The solution of Eq. (2) is

$$\phi=(\sin kr/k)+Se^{ikr}, \tag{2.2}$$

where the normalization of ϕ has been chosen so that the first term on the right-hand side corresponds to the S-wave part of a plane wave of unit amplitude, i.e., $\exp i\mathbf{kr}\cong\sin kr/kr$ for $kr\ll 1$; S is the amplitude of the scattered (outgoing) wave.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In the internal region $r<R$, ϕ can be obtained as

$$\phi(r)=\sum a_m\phi_m(r), \quad r<R, \tag{3}$$

where the ϕ_m are eigenfunctions satisfying the equation

$$\frac{h^2}{2M}\frac{d^2\phi_m}{dr^2}+(E_m-V)\phi_m=0, \tag{3.1}$$

and the boundary condition

$$\left\{\frac{d\phi_m}{dr}=ik\phi_m\right\}\Bigg|_{r=R}. \tag{3.2}$$

The eigenvalues E_m are complex because of this imaginary boundary condition, the boundary condition depending explicitly on the wave number and hence, the energy of the incident neutron. We discuss the consequences of this later. These eigenfunctions form a complete set.[15] Orthogonality of the ϕ_m is easily established by considering the equation for ϕ_n,

$$\frac{h^2}{2M}\frac{d^2\phi_n}{dr^2}+(E_n-V)\phi_n=0, \tag{3.3}$$

multiplying Eq. (3.1) on the left by ϕ_n and Eq. (3.3) on the left by ϕ_m and subtracting. Thus,

$$\frac{h^2}{2M}\left(\phi_n\frac{d^2\phi_m}{dr^2}-\phi_m\frac{d^2\phi_n}{dr^2}\right)+(E_m-E_n)\phi_n\phi_m=0. \tag{3.4}$$

By integrating this equation from 0 to R and using Green's theorem, one finds that

$$\frac{h^2}{2M}\left(\phi_n\frac{d\phi_m}{dr}-\phi_m\frac{d\phi_n}{dr}\right)_{r=R}=(E_n-E_m)\int_0^R\phi_n\phi_m dr. \tag{3.5}$$

From Eq. (3.2) it can be seen that the left-hand side vanishes and hence

$$\int_0^R\phi_n(r)\phi_m(r)dr=0, \quad E_m\neq E_n. \tag{3.6}$$

In general, $E_m\neq E_n$ implies $m\neq n$; the exceptional case $E_n=E_m$ for $m\neq n$ can be handled by special methods, but it does not occur for the type of potentials we consider. For $m=n$, we choose the normalization of the ϕ_m's so that the integral is equal to unity, i.e.,

$$\int_0^R\phi_m^2(r)dr=1. \tag{3.7}$$

Two important features are first, the orthogonality is between ϕ_n and ϕ_m, not ϕ_n^* and ϕ_m as is usually the case, and secondly, the orthogonality depends essentially on the fact that ϕ_m and ϕ_n obey the same boundary condition.

[15] R. E. Peierls, Proc. Cambridge Phil. Soc. 44, 242 (1948).

By using the orthogonality of the ϕ_m we can obtain the a_m of Eq. (3) by again using Green's theorem.

$$\int_0^R(\phi_m\mathfrak{L}\phi-\phi\mathfrak{L}\phi_m)dr=-\frac{h^2}{2M}\left(\phi_m\frac{d\phi}{dr}-\phi\frac{d\phi_m}{dr}\right)_R, \tag{4}$$

with

$$\mathfrak{L}=-\frac{h^2}{2M}\frac{d^2}{dr^2}+V(r). \tag{4.1}$$

From Eqs. (1) and (3.1), one obtains

$$(E-E_m)a_m=-\frac{h^2}{2M}\left[\left(\frac{d\phi}{dr}-ik\phi\right)\phi_m\right]_R$$

$$=-\frac{h^2}{2M}e^{-ikR}\phi_m(R), \tag{4.2}$$

giving

$$a_m=\frac{h^2}{2M}\frac{e^{-ikR}}{E_m-E}\phi_m(R). \tag{4.3}$$

The joining of the inside and outside solutions at $r=R$ gives

$$\sum a_m\phi_m(R)=\frac{\sin kR}{k}+Se^{ikR}, \tag{5}$$

giving

$$S=\frac{1}{ke^{ikR}}\left\{\sum_m\frac{kh^2}{2M}e^{-ikR}\frac{[\phi_m(R)]^2}{E_m-E}-\sin kR\right\}. \tag{6}$$

This can be put into familiar form by defining the width

$$\Gamma_m\equiv\frac{kh^2}{M}[\phi_m(R)]^2. \tag{6.1}$$

Then

$$S=\frac{e^{-2ikR}}{2k}\sum_m\frac{\Gamma_m}{E_m-E}-\frac{\sin kR}{k}e^{-ikR}, \tag{7}$$

and

$$\sigma=4\pi|S|^2. \tag{7.1}$$

Because of the imaginary boundary condition, the ϕ_m and hence the Γ_m are complex. For low bombarding energies, the imaginary part is small as appears later.

The imaginary part of E_m can be found by the development

$$\int_0^R(\phi_m\mathfrak{L}\phi_m^*-\phi_m^*\mathfrak{L}\phi_m)dr$$

$$=(E_m^*-E_m)\int_0^R\phi_m\phi_m^*dr. \tag{8}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

From Green's theorem, the left-hand side is

$$(ik\hbar^2/M)\phi_m^*\phi_m(R),$$

and if the imaginary part of E_m is denoted by $-\beta_m/2$, i.e.,

$$E_m=\epsilon_m-i\beta_m/2, \tag{8.1}$$

then from Eq. (8) we find that

$$\beta_m=\frac{k\hbar^2}{M}\frac{|\phi_m(R)|^2}{\int_0^R|\phi_m(r)|^2dr}. \tag{8.2}$$

This has a simple interpretation. The numerator is proportional to the escape velocity of the particle $k\hbar/M$ multiplied by the probability of the particle being at the surface, whereas the denominator represents the probability of the particle being in the nucleus. At low energies where the ϕ_m are mainly real, as already indicated, the denominator is nearly unity [see Eq. (3.7)] and comparing Eqs. (8.2) and (6.1), we see that

$$\beta_m\cong\Gamma_m \quad \text{(low energies)}. \tag{8.3}$$

To obtain a better idea of the sizes of the various quantities, it is useful to illustrate the formalism by evaluating them for a square well. We choose a well $V=-U$, $r<R_0$; $V=0$, $r>R_0$; with $U=42$ Mev and $R_0=1.45$ A$^{\frac{1}{3}}$ $\times10^{-13}$ cm, where A is the atomic number; these are the parameters of the well employed by Feshbach, Porter, and Weisskopf,[9] aside from the imaginary part employed by them which is introduced later. Consequently, these parameters are typical of those considered later. The solution of Eqs. (3.1) and (3.2) are compared later with $\phi_m^{(0)}$ defined by

$$\frac{\hbar^2}{2M}\frac{d^2}{dr^2}\phi_m^{(0)}(r)+(E_m^{(0)}-V)\phi_m^{(0)}(r)=0, \tag{9}$$

$$\left.\frac{d\phi_m^{(0)}}{dr}\right|_{r=R}=0. \tag{9.1}$$

This real boundary condition is that of the Wigner-Eisenbud theory, and the solutions $\phi_m^{(0)}$ are real. The functions $\phi_m^{(0)}$ are considered because it is easier to calculate these real functions and, at low energies, they are a good zero-order approximation to ϕ_m as we show.

In the square well ϕ_m is equal to

$$\phi_m=A_m\sin(K_m-i\kappa_m)r, \tag{9.2}$$

with K_m and κ_m defined by

$$(K_m-i\kappa_m)^2=2M(E_m+U)/\hbar^2. \tag{9.3}$$

For simplicity, the joining radius R in Eq. (3.2) has been chosen to be the edge of the well, R_0. It can be chosen differently and is generally chosen somewhat larger, but this is immaterial for the qualitative features of the results derived here. The boundary condition, Eq. (3.2), can now be written

$$(K_m-i\kappa_m)\cos(K_m-i\kappa_m)R=ik\sin(K_m-i\kappa_m)R. \tag{9.4}$$

Now κ_mR is shown to be small at low energies; Eq. (9.4) is expanded to first order in this quantity. Then

$$(K_m-i\kappa_m)(\cos K_mR+i\kappa_mR\sin K_mR)\cong ik(\sin K_mR-i\kappa_mR\cos K_mR). \tag{9.5}$$

This gives

$$\kappa_m=k\sin K_mR/(K_mR\sin K_mR-\cos K_mR). \tag{9.6}$$

Since $\cos K_mR\ll K_mR\sin K_mR$ [see Eq. (9.8)], it follows that

$$\kappa_m\cong k/K_mR. \tag{9.7}$$

By using this value for κ_m, one obtains from Eq. (9.5)

$$\cos K_mR\cong-(kR)^2\sin K_mR/(K_mR)^3 \tag{9.8}$$

to lowest order in κ_mR. Now K_mR is large, of the order of 10 even for medium A and zero incident energy, and so κ_m and $\cos K_mR$ are small. Equation (9.7) shows that κ_mR is small—which is necessary for the rapid convergence of the expansion above—as long as $E\ll U$, that is, as long as the bombarding energy is much less than the depth of the well.

We now let $K_mR=K_m^{(0)}R+\delta K_mR$, where $\phi_m^{(0)}=(2/R)^{\frac{1}{2}}\sin K_m^{(0)}R$, and $K_m^{(0)}R=(n+\frac{1}{2})\pi$ gives a solution to Eqs. (9) and (9.1). To lowest order in κ_mR, Eq. (9.8) shows that

$$\delta K_m=k[kR/(K_mR)^3]. \tag{9.9}$$

Although this is a second-order correction (in the sense that δK_mR is of second order in kR), it is given correctly to this order by our first-order expression Eq. (9.5), since further terms enter only in third order. We find, further, that

$$\delta\epsilon_m\equiv\epsilon_m-E_m^{(0)}=(\hbar^2/2M)(2K_m\delta K_m-\kappa_m^2)\cong[1/(K_mR)^2]\epsilon_m, \tag{9.10}$$

where the energies are measured from the bottom of the well. For a typical value of K_mR of ~10, this means that calculation of the real part of the resonance energy from the boundary condition Eq. (9.1) gives results accurate to $\sim1\%$.

The imaginary part β_m of E_m is given to first order in κ_mR by $(\hbar^2k/M)[\phi_m^{(0)}(R)]^2$ which is equal to

$$\beta_m\cong2\hbar^2k/MR\cong\Gamma_m, \tag{9.11}$$

since

$$\phi_m^{(0)}(r)=(2/R)^{\frac{1}{2}}\sin K_mr. \tag{9.12}$$

Thus, to lowest order in κ_mR, the Γ_m are real and the dependence of the real parts of the resonance energies ϵ_m on the bombarding energy enters only in the second order of this quantity.

Generalization of these results to the case of a

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

complex square well is trivial. The introduction of $\tilde{V}(r)=-U-iW$ (use $\tilde{V}$ to denote a complex well; eigenfunctions in this complex well are denoted by $\tilde{\phi}_m(r)$, etc.) so that W simply shifts the resonance energy by the constant amount $-iW$. Hence,

$$\tilde{E}_m=E_m-iW=\epsilon_m-i\beta_m/2-iW. \quad (9.13)$$

Consequently, introduction of an imaginary part broadens the resonance levels. The eigenfunctions are unchanged, i.e., $\tilde{\phi}_m(r)=\phi_m$ in the special case of the square well. The development for the case in which the real and imaginary parts vary with r is easily carried out. This development can also be carried out for complex velocity-dependent potentials[16]; this is important since the parameters of the optical model wells occurring in practice depend on the bombarding energy. It is convenient to take the depth of the well to be different for the different eigenenergies at a given bombarding energy. In discussing a velocity-dependent well $\tilde{V}(r)$, one can consider $\tilde{V}$ to be a nonlocal operator $\tilde{V}(\mathbf{r}',\mathbf{r})$, which is equivalent to a velocity-dependent potential. The wave equation is

$$\frac{\hbar^2}{2M}\frac{d^2}{dr'^2}\tilde{\phi}_m(r')+\tilde{E}_m\tilde{\phi}_m(r')-\int\tilde{V}(\mathbf{r}',\mathbf{r})\tilde{\phi}_m(r)dr=0. \quad (10)$$

Orthogonality of the $\tilde{\phi}_m$ requires $\tilde{V}(\mathbf{r}',\mathbf{r})=\tilde{V}(\mathbf{r},\mathbf{r}')$; potentials not obeying this relation can be shown to be physically unreasonable.[16] Proof of orthogonality assumes $\tilde{V}(\mathbf{r},\mathbf{r}')$ to be zero unless both r and r' are less than R.

The resonance treatment for a neutron in the complex potential has been developed in some detail, not only to illustrate the formalism, but also because knowledge of the positions, widths, and spacings of the levels is often useful in theoretical estimates.

Generalization of these results to the case of nonzero angular momentum is easy. In this case we express the function, regular at the origin, $\psi_\alpha(\mathbf{r})$ as

$$r\psi_\alpha(\mathbf{r})=\Theta_\alpha(\theta,\varphi)\phi_\alpha(r), \quad (11)$$

where $\Theta_\alpha(\theta,\varphi)$ is the normalized function of angles, e.g., in the case of spinless particles, $\Theta_\alpha(\theta,\varphi)$ is equal to $Y_l^m(\theta,\varphi)$, where Y_l^m is the normalized spherical harmonic, and ϕ_α is the radial function in the potential well, regular at the origin and asymptotic to

$$e^{i\delta_l}\sin[kr-(l\pi/2)+\delta_l],$$

where δ_l is the phase shift for the lth wave. The lower index α labels all angular momentum quantum numbers, i.e., in the terminology of Wigner and co-workers, it is the "channel" index. Further, solutions asymptotic to outgoing waves are denoted by $\psi^+(\mathbf{r})$, i.e.,

$$r\psi_\alpha^+(\mathbf{r})=\Theta_\alpha(\theta,\varphi)\phi_\alpha^+(r), \quad (11.1)$$

where $\phi_\alpha^+(r)$ is asymptotic to $\exp(ikr-il\pi/2)$ in the case of neutrons. Generalization to the case of charged particles is easily made. Here $\phi_\alpha^+(r)$ is asymptotic to $\exp(ikr-\eta\ln 2kr-l\pi/2+\sigma_l)$ where $\eta=Ze^2/\hbar v$, with v the velocity of the proton, and σ_l is the Coulomb phase shift. Solution of the radial Schrödinger equation can be expressed for $r>R$, as

$$\phi_\alpha(r)=[\phi_\alpha^+(r)-\phi_\alpha^-(r)]/2ik+S_\alpha\phi_\alpha^+(r), \quad (12)$$

with $\phi_\alpha^-=(\phi_\alpha^+)^*$, the solution asymptotic to incoming waves. The eigenfunctions ϕ_m (these have the same angular dependence as the $\phi_\alpha(r)$, so we do not carry the subscript α on them) are then determined by the boundary condition

$$\left[\frac{d\phi_m}{dr}=f_\alpha^+(r)\phi_m\right]_{r=R} \quad (12.1)$$

where

$$f_\alpha^+(r)=\frac{1}{\phi_\alpha^+(r)}\frac{d\phi_\alpha^+(r)}{dr} \quad (12.2)$$

is the logarithmic derivative for an outgoing wave at the joining radius. Again, $\phi_\alpha(r)$ can be expanded in terms of the ϕ_m,

$$\phi_\alpha(r)=\sum_m a_m\phi_m(r), \quad r<R, \quad (12.3)$$

and the development analogous to that of Eqs. (4) to (4.3) now gives

$$(E-E_m)a_m=-\frac{\hbar^2}{2M}\left[\left(\frac{d\phi_\alpha}{dr}-f^+\phi_\alpha\right)\phi_m\right]_R. \quad (12.4)$$

The use of Eq. (12) for ϕ_α leaves only the term in ϕ_α^- on the right-hand side of Eq. (12.4), and we obtain

$$(E-E_m)a_m=\frac{\hbar^2}{4Mik}[(f_\alpha^--f_\alpha^+)\phi_\alpha^-\phi_m]_R. \quad (12.5)$$

The Wronskian is

$$[f_\alpha^+(r)-f_\alpha^-(r)]\phi_\alpha^+(r)\phi_\alpha^-(r)=2ik, \quad (12.6)$$

so that we obtain

$$a_m=\frac{\hbar^2}{2M}\frac{1}{\phi_\alpha^+(R)}\frac{\phi_m(R)}{(E_m-E)}. \quad (12.7)$$

The joining of the inside and outside solutions at $r=R$ now gives

$$S_\alpha=\frac{1}{k[\phi_\alpha^+(R)]^2}\sum_m\frac{k\hbar^2}{2M}\frac{\phi_m^2(R)}{E_m-E}-\frac{\phi_\alpha^+(R)-\phi_\alpha^-(R)}{2ik\phi_\alpha^+(R)}. \quad (12.8)$$

We define

$$\Gamma_m\equiv\frac{k\hbar^2}{M}P(R)\phi_m^2(R), \quad (12.9)$$

[16] See Appendix C of G. E. Brown and C. T. De Dominicis, Proc. Phys. Soc. (London) A72, 70 (1958).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where P is the penetrability,

$$P=\frac{1}{\phi_\alpha^+(R)\phi_\alpha^-(R)}=\frac{1}{|\phi_\alpha^+(R)|^2}. \tag{12.10}$$

We then have

$$S_\alpha=\frac{1}{2k}\frac{\phi_\alpha^-(R)}{\phi_\alpha^+(R)}\sum_m\frac{\Gamma_m}{E_m-E}-\frac{1}{2ik}\left(1-\frac{\phi_\alpha^-(R)}{\phi_\alpha^+(R)}\right). \tag{12.11}$$

The cross section is given by

$$\sigma_\alpha=4\pi|S_\alpha|^2$$
$$=\frac{\pi}{k^2}\left|\frac{\phi_\alpha^-(R)}{\phi_\alpha^+(R)}\sum_m\frac{\Gamma_m}{E_m-E}+i\left(1-\frac{\phi_\alpha^-(R)}{\phi_\alpha^+(R)}\right)\right|^2. \tag{12.12}$$

2. The Many-Body Case

We consider the case in which an incident nucleon is scattered either elastically or inelastically by a nucleus of A particles.[17] Once this particle is inside the radius R —which is chosen so that the interaction between the incident particle and the nucleus vanishes outside this radius—the wave function can again be expanded in compound states $\Phi^{(p)}(\mathbf{r},\xi)$. Here we use $\mathbf{r}$ for the coordinate of the incident nucleon and ξ to label the totality of coordinates of the A particles inside the nucleus. For the moment the incident particle is treated as distinguishable from those in the nucleus, but later the generalization to the case where it is identical with particles in the nucleus is indicated.

The compound states $\Phi^{(p)}(\mathbf{r},\xi)$ obey the equations

$$H\Phi^{(p)}(\mathbf{r},\xi)=W_p\Phi^{(p)}(\mathbf{r},\xi),$$
$$H=H_\xi+T(r)+V(\mathbf{r},\xi). \tag{13}$$

H_ξ is the Hamiltonian of the A nuclear particles, $T(r)$ is the kinetic energy of the incident particle, and $V(\mathbf{r},\xi)$ is the potential interaction between the A nuclear particles and the incident nucleon. It is a sum of nucleon-nucleon potentials,

$$V(\mathbf{r},\xi)=\sum_{i=1}^{A}V(\mathbf{r},\mathbf{r}_i),$$

the nucleon to which the coordinate $\mathbf{r}$ refers being the incident particle. It is assumed that $V(\mathbf{r},\xi)$ is a well-behaved potential, i.e., a potential without a strong repulsive core and other singularities; generalization to the case that it is not can be made using techniques developed by Watson and Brueckner, but this only introduces nonessential complications for the points considered here.

[17] The emission of composite particles is dropped from the dispersion-theory description later on when one makes the assumption that the interaction between the incident particle and all of the A particles vanishes beyond the joining radius R. These processes can presumably be included by modifying the formalism.

States $\Phi^{(p)}$ and $\Phi^{(q)}$ are not now orthogonal, but rather $\Phi^{(p)}$ and $\bar{\Phi}^{(q)}$, where $\bar{\Phi}^{(q)}$ is obtained from $\Phi^{(q)}$ by taking the complex conjugate of all functions of angles, in particular, of the $\Theta_\alpha(\theta,\varphi)$ occurring in the single-particle function. Equivalently, to within an arbitrary phase factor, $\bar{\Phi}^{(q)}$ is obtained from $\Phi^{(q)}$ by rotating the wave function so that the total angular momentum component M is changed into $-M$ without taking the complex conjugate of the function of intrinsic structure (e.g., the radial wave function in the single-particle case). We choose

$$\int_0^R\bar{\Phi}^{(q)}\Phi^{(p)}d^3\xi d^3r=1,\quad(p=q), \tag{13.1}$$

and the integral is zero for $p\neq q$. In using the orthogonality later on, we do not indicate the bar over the Φ on the left since the change in the angular momentum functions is a trivial one to introduce once we introduce the expansion, Eq. (14), and all integrals over angles are easy to carry out.

We introduce a complete set of states $\chi_j(\xi)$ for the A particles. Boundary conditions for these states could be chosen in various ways. However, the tightly bound states close to the ground state in which we are mainly interested are insensitive to the precise boundary condition, e.g., if we choose the joining radius R fairly far out, then both the wave function and its derivative are small for a bound state defined in any sensible way, and it would not matter much whether we chose the former or the latter to be zero, or to have some small finite value at that radius as our boundary condition. Difficulties enter when the excitation energy ϵ_j, which we measure from ϵ_0 as origin, of the state χ_j is sufficiently large so that one of the A particles can escape from the nucleus. However, since the only property of these highly excited states that we use is that they, together with those of low excitation, form a complete set, we believe our results to be independent of the way in which these boundary conditions are chosen.

In order to make the connection with the optical model later, it is convenient to employ states $\tilde{\psi}_m(\mathbf{r})$ in a complex well of the type discussed in the last section for the incident particle. We can then expand

$$\Phi^{(p)}(\mathbf{r},\xi)=\sum_{j,m}a_{jm}{}^p\chi_j(\xi)\tilde{\psi}_m{}^j(\mathbf{r}). \tag{14}$$

The boundary condition on $\Phi^{(p)}$ at $r=R$ can now be simply stated in terms of the boundary conditions on the $\tilde{\psi}_m{}^j$. It is convenient, in analogy with Eq. (11), to introduce radial functions $\tilde{\phi}_m$ through

$$r\tilde{\psi}_m{}^j(\mathbf{r})=\Theta_\alpha(\theta,\varphi)\tilde{\phi}_m{}^j(r). \tag{14.1}$$

The boundary condition is then

$$\left[\frac{d\tilde{\phi}_m{}^j}{dr}=f_\alpha^+(r,E-\epsilon_j)\tilde{\phi}_m{}^j(r)\right]_{r=R}. \tag{14.2}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The $E-\epsilon_j$ in the argument of f_α^+ indicates that it is to be taken for that energy. The boundary condition is chosen to be that of an outgoing wave at the reduced energy available to the outgoing particle after leaving the residual nucleus in excited state j. The channel index α on the $\tilde{\psi}_m{}^j$ is again suppressed. Because of the dependence of f_α^+ on ϵ_j, the $\tilde{\psi}$'s also depend on j, as indicated; however, this dependence is weak. The fact that the boundary condition on the $\tilde{\psi}$'s depends on j does not upset the orthogonality of the $\Phi^{(p)}$'s as long as one always integrates over the ξ coordinates first.

We can express the wave function $\Psi(\mathbf{r},\xi)$, which is the solution to the Schrödinger equation,

$$H\Psi=E\Psi, \tag{15}$$

as

$$\Psi(\mathbf{r},\xi)=\sum a_p\Phi^{(p)}(\mathbf{r},\xi) \quad \text{for } r<R, \tag{15.1}$$

and as

$$\Psi(\mathbf{r},\xi)=I_\alpha\left(\frac{\psi_\alpha^+(\mathbf{r})-\psi_\alpha^-(\mathbf{r})}{2ik}\right)\chi_o(\xi)+S_\alpha\psi_\alpha^+(\mathbf{r})\chi_o(\xi)$$
$$+\sum_{\alpha\neq\alpha'} S_{\alpha\alpha',j}\psi_{\alpha'}{}^{j+}(\mathbf{r})\chi_j(\xi) \quad \text{for } r>R, \tag{15.2}$$

where S_α is the amplitude for elastic scattering in channel α and $S_{\alpha\alpha',j}$ is the amplitude for inelastic scattering from channel α into channel α', leaving the nucleus excited in state χ_j. The $\psi_{\alpha'}{}^{j+}$ represents an outgoing wave at energy $E-\epsilon_j$ in channel α'. The coefficient I_α represents the amplitude for channel α in the plane wave. In the case of spinless particles,

$$e^{i\mathbf{k}\cdot\mathbf{r}}=\sum_{l=0}^{\infty} i^l[4\pi(2l+1)]^{\frac{1}{2}}Y_l{}^0(\theta,\varphi)j_l(kr). \tag{15.3}$$

If we set $\alpha=l$, i.e., identify $Y_l{}^0$ with Θ_α for this case, and use

$$j_l\sim\frac{\sin(kr-l\pi/2)}{kr}, \tag{15.4}$$

we choose

$$I_l=i^l(2l+1)^{\frac{1}{2}} \tag{15.5}$$

for this special case. The $(4\pi)^{\frac{1}{2}}$ is taken into account at a later stage by multiplying by 4π to obtain the cross section, as in Eqs. (7.1) and (12.12); this convention makes our general treatment correspond to our S-wave case when $l=0$.

We can again find the a_p by Green's theorem,

$$\int_0^R(\Phi^{(p)}H\Psi-\Psi H\Phi^{(p)})d^3\xi d^3r=(E-W_p)a_p$$
$$=-\frac{h^2}{2M}\sum_{j,m}a_{jm}{}^p\int_0^R d^3\xi\chi_j(\xi)$$
$$\times\int d\Omega\left\{R\tilde{\psi}_m{}^j(\mathbf{R})\frac{d}{dr}[r\Psi(\mathbf{r},\xi)]\right.$$
$$\left.-R\Psi(\mathbf{R},\xi)\frac{d}{dr}[r\tilde{\psi}_m{}^j(\mathbf{r})]\right\}_{r=R}. \tag{16}$$

With the use of Eq. (14.2), we find

$$a_p=\frac{h^2}{2M(W_p-E)}\sum_{j,m}a_{jm}{}^p\int_0^R d^3\xi\chi_j(\xi)\int d\Omega$$
$$\times\left\{R\tilde{\psi}_m{}^j(\mathbf{R})\left[\frac{d}{dr}-f_\alpha^+(R,E-\epsilon_j)\right]r\Psi(\mathbf{r},\xi)\right\}_{r=R}, \tag{16.1}$$

where we have indicated the energy dependence of the f_α^+ explicitly. The operator in [ ]'s in Eq. (16.1) gives zero operating on any "outgoing" part of Ψ, and the only term that contributes in Eq. (15.2) is the term in $\psi_\alpha^-(\mathbf{r})\chi_o(\xi)$. Hence, using the orthogonality of the χ's,

$$a_p=-I_\alpha\frac{h^2}{2M(W_p-E)}\sum_m a_{om}{}^p\left\{\frac{f_\alpha^-(R)-f_\alpha^+(R)}{2ik}\right\}$$
$$\times\int d\Omega R\tilde{\psi}_m(\mathbf{R})R\psi_\alpha^-(\mathbf{R}). \tag{16.2}$$

The integral over Ω guarantees that the angular dependence of the $\tilde{\psi}_m$ is the same as that of the incident channel α. With this restriction understood, we can write a_p in terms of the radial part of the wave functions,

$$a_p=I_\alpha\frac{h^2}{2M(W_p-E)}\left\{\frac{f_\alpha^--f_\alpha^+}{2ik}\right\}\phi_\alpha^-(R)\sum_m a_{om}{}^p\tilde{\phi}_m(R). \tag{16.3}$$

We can simplify Eq. (16.3) by using the Wronskian, Eq. (12.6), giving

$$a_p=I_\alpha\frac{h^2}{2M(W_p-E)}\frac{1}{\phi_\alpha^+(R)}\sum_m a_{om}{}^p\tilde{\phi}_m(R). \tag{16.4}$$

By having a_p, we can now obtain S_α and $S_{\alpha\alpha',j}$ by matching the internal and external wave functions, Eqs. (15.1) and (15.2), at the joining radius. If both equations are multiplied by $\chi_o(\xi)$ and $R\Theta_\alpha$ and integrated over $d^3\xi$ and $d\Omega$, one obtains

$$S_\alpha\phi_\alpha^+(R)=\sum_p a_p\sum_{m'}a_{om'}{}^p\tilde{\phi}_{m'}(R)$$
$$-I_\alpha(\phi_\alpha^+(R)-\phi_\alpha^-(R))/2ik. \tag{17}$$

If we introduce the width,

$$\gamma_p=\frac{kh^2}{M}\frac{1}{\phi_\alpha^+(R)\phi_\alpha^-(R)}\sum_m\sum_{m'}a_{om}{}^pa_{om'}{}^p\tilde{\phi}_m(R)\tilde{\phi}_{m'}(R), \tag{17.1}$$

we can write

$$S_\alpha=\frac{I_\alpha\phi_\alpha^-(R)}{2k\,\phi_\alpha^+(R)}\sum_p\frac{\gamma_p}{W_p-E}-\frac{I_\alpha}{2ik}\left(1-\frac{\phi_\alpha^-(R)}{\phi_\alpha^+(R)}\right), \tag{18}$$

which is of the same form as Eq. (12.11). The cross

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

section σ_α for elastic scattering is given by

$$\sigma_\alpha = 4\pi |S_\alpha|^2. \tag{18.1}$$

For spinless particles, α can be replaced by the label l, and with the value of I_l given by Eq. (15.5), one obtains

$$\sigma_l = (2l+1)\frac{\pi}{k^2}\left|\frac{\phi_l^-(R)}{\phi_l^+(R)}\sum_p \frac{\gamma_p}{W_p - E} + i\left(1 - \frac{\phi_l^-(R)}{\phi_l^+(R)}\right)\right|^2, \tag{18.2}$$

for the total scattering through channel l. Since the incident particle is described by a plane wave, Eq. (15.3), the differential cross section is given as the square of a sum of terms involving different l,[18]

$$\frac{d\sigma(\theta)}{d\Omega} = 4\pi \left|\sum_l i^{-l} S_l Y_l^0\right|^2. \tag{18.3}$$

Similarly, the amplitude for inelastic scattering is

$$S_{\alpha\alpha',j} = \frac{1}{\phi_{\alpha'}{}^{j+}(R)} \sum_p a_p \sum_m a_{jm}{}^p \tilde{\phi}_m{}^j(R). \tag{19}$$

In the inelastic case, the widths do not occur naturally in the amplitude, but if quantities u_p and u_{pj} are defined by

$$u_p = \left(\frac{kh^2}{M}\right)^{\frac{1}{2}} \frac{1}{|\phi_\alpha{}^+(R)|} \sum_m a_{om}{}^p \tilde{\phi}_m(R), \tag{19.1}$$

and

$$u_{pj} = \left(\frac{k_j h^2}{M}\right)^{\frac{1}{2}} \frac{1}{|\phi_{\alpha'}{}^{j+}(R)|} \sum_m a_{jm}{}^p \tilde{\phi}_m{}^j(R), \tag{19.1}$$

then

$$\sigma_{\alpha\alpha',j} = \frac{4\pi k_j}{k}|S_{\alpha\alpha',j}|^2 = \frac{\pi}{k^2}\left|I_\alpha \sum_p \frac{u_p u_{pj}}{W_p - E}\right|^2. \tag{19.2}$$

The ratio k_j/k, with k_j defined by $k_j{}^2 = 2M(E-\epsilon_j)/\hbar^2$, is the ratio of the velocity of the outgoing particle to that of the incident one, which enters into the cross section.

In case one term, p, in the sum in Eq. (19.2) contributes the main part of the sum, the inelastic cross section can be put into the form of the Breit-Wigner formula

$$\sigma_{\alpha\alpha',j} = \frac{\pi}{k^2}|I_\alpha|^2 \frac{\gamma_p \gamma_{pj}}{|W_p - E|^2}. \tag{19.3}$$

(See the Breit-Wigner formula given in the introduction; there we indicated the channel index on the γ's explicitly.) In Eq. (19.3)

$$\gamma_p = u_p{}^2,$$

as previously, and

$$\gamma_{pj} = u_{pj}{}^2 \tag{19.4}$$

is the width for the inelastic process.

Now $W_p = \epsilon_p - i\alpha_p/2$, where ϵ_p and α_p are real, and we are interested in the width α_p. This can be obtained from the original and conjugate equations,

$$(H - W_p)\Phi^{(p)} = 0, \tag{20}$$
$$(H - W_p{}^*)\Phi^{(p)*} = 0.$$

If the first equation is multiplied on the left by $\Phi^{(p)*}$ and the second by $\Phi^{(p)}$, one obtains, after subtracting and integrating,

$$i\alpha_p \int_0^R \Phi^{(p)*}\Phi^{(p)} d^3\xi d^3r = \frac{\hbar^2}{2M}\int d^3\xi \int d\Omega \times \left[r\Phi^{(p)*}\frac{d}{dr}(r\Phi^{(p)}) - r\Phi^{(p)}\frac{d}{dr}(r\Phi^{(p)*})\right]_{r=R}. \tag{21}$$

By using the expansion Eq. (14) and the boundary conditions Eq. (14.2), this becomes

$$i\alpha_p \int_0^R \Phi^{(p)*}\Phi^{(p)} d^3\xi d^3r = \frac{\hbar^2}{2M}\sum_{j,m,m'} a_{jm}{}^{p*} a_{jm'}{}^p \tilde{\phi}_m{}^{j*}(R)\tilde{\phi}_m{}^j(R) \times [f_{\alpha'}{}^+(E-\epsilon_j, R) - f_{\alpha'}{}^-(E-\epsilon_j, R)]. \tag{22}$$

Use of the Wronskian, Eq. (12.6), results in

$$\alpha_p = \frac{\hbar^2}{M}\sum_{j,m,m'} \frac{k_j a_{jm}{}^{p*} a_{jm'}{}^p \tilde{\phi}_m{}^{j*}(R)\tilde{\phi}_{m'}{}^j(R)/\phi_{\alpha'}{}^{j+}(R)\phi_{\alpha'}{}^{j-}(R)}{\int_0^R \Phi^{(p)*}\Phi^{(p)} d^3\xi d^3r}, \tag{22.1}$$

where the sum over j includes the term $j=0$. The right-hand side of Eq. (22.1) has a simple interpretation similar to that of Eq. (8.2). In the numerator the jth term in the sum is proportional to the probability of the particle being at the radius R, multiplied by its escape velocity and the relevant penetrability. The integral in the denominator represents the probability of the particle in compound state p being in the nucleus. (The normalization is such that this probability is not

[18] The factor i^{-l} enters because S_l is the coefficient of $\exp(ikr - il\pi/2)$, so that the coefficient of $\exp ikr$ is

$$S_l \exp(-il\pi/2) = S_l i^{-l}.$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

necessarily unity.) In the low-energy region where all of the quantities on the right-hand side of Eq. (22.1) are essentially real, as is shown later, this reduces to

$$\alpha_p=\sum_j \gamma_{pj}. \tag{22.2}$$

This is interpreted as the total width being equal to the sum of partial widths for the various processes.

Equation (18) is similar to a many-level Breit-Wigner formula. This relationship between the scattering amplitude and the sum of resonance terms is linear, and this is why it is often simpler to employ in the many-level case than the Wigner-Eisenbud expressions. However, before it can be applied to the case in which only one or two levels contribute, as in the application to low-energy reactions with light nuclei, it is sometimes necessary to make the energy dependence of the γ_p's (which results from the dependence of the boundary conditions on E) explicit, and to determine the imaginary part [the γ_p's defined by Eq. (17.1) are complex]. The determination of these is equivalent to relating the formalism back to the Wigner-Eisenbud one in which the widths are real and independent of energy. The approximate relationship was developed in perturbation theory by Kapur and Peierls,[3] but we prefer to use a procedure developed by A. M. Lane.[19] States $\tilde{\psi}_m{}^{j(0)}(\mathbf{r})$ are defined for which the radial part, multiplied by r, obeys the energy-independent boundary condition

$$\left[\frac{d}{dr}r\tilde{\phi}_m{}^{j(0)}(r)=0\right]_{r=R}, \tag{23}$$

in analogy with Eq. (9.1). By building up $\Phi_0{}^{(q)}$ as

$$\Phi_0{}^{(q)}(\mathbf{r},\xi)=\sum_{j,m} a_{jm}{}^{q(0)}\chi_j(\xi)\tilde{\psi}_m{}^{j(0)}(\mathbf{r}), \tag{23.1}$$

we define energy-independent compound states. The overlap between such states and our energy-dependent compound states can be found by employing Green's theorem again as in Eq. (16). This gives

$$(W_p-W_q{}^{(0)})\int_0^R \Phi_0{}^{(q)}\Phi^{(p)}d^3\xi d^3r$$
$$=-\frac{h^2}{2M}\int_0^R d^3\xi\int d\Omega\left\{R\Phi_0{}^{(q)}(\mathbf{R},\xi)\times\frac{d}{dr}[r\Phi^{(p)}(\mathbf{r},\xi)]\right\}_{r=R}. \tag{23.2}$$

For the case in which the resonances p are well separated and only S-wave scattering can occur, we have

$$(W_p-W_q{}^{(0)})\int_0^R \Phi_0{}^{(q)}\Phi^{(p)}d^3\xi d^3r$$
$$=-\frac{ih^2}{2M}\sum_{j,m,n} k_j a_{jm}{}^{q(0)}a_{jn}{}^{p}\tilde{\phi}_m{}^{j(0)}(R)\tilde{\phi}_n{}^{j}(R). \tag{24}$$

This equation is exact, but we now use perturbation theory starting with the zero-order approximation $\Phi^{(p)}=\Phi_0{}^{(p)}$. To obtain the first-order correction to the energy, we let $p=q$ and set $\Phi_0{}^{(p)}$ equal to $\Phi^{(p)}$ under the integral. This gives

$$W_p-W_p{}^{(0)}\cong -i\alpha_p/2,$$

where we have used Eq. (22.1) and remembered that the $a_{jn}{}^{(p)}$ and $\tilde{\phi}_m{}^j$ are real in this approximation. Hence, the first-order correction to the energy simply adds an imaginary part which is just the width of the state $\Phi^{(p)}$ and which is independent of energy in this order. We can obtain the first-order correction to the wave function by expanding

$$\Phi^{(p)}=\Phi_0{}^{(p)}+\sum c_q{}^p\Phi_0{}^{(q)}, \tag{24.1}$$

and we obtain

$$(W_p-W_q{}^{(0)})c_q{}^p=-\frac{ih^2}{2M}\sum_{j,m,n} k_j a_{jm}{}^{q(0)}a_{jn}{}^{p}\times\tilde{\phi}_m{}^{j(0)}(R)\tilde{\phi}_n{}^{j}(R), \quad (p\neq q). \tag{24.2}$$

The right-hand side is of order $-i\alpha_p/2$, its approximate size for $p=q$, or less. (The signs of the $a_{jm}{}^{q(0)}$ and the $a_{jn}{}^{p}$ can be both positive and negative, and this tends to make the right-hand side smaller than $-i\alpha_p/2$. If a random-phase approximation were applicable, the right-hand side would be zero.) Therefore, for order of magnitude we have

$$c_q{}^p\sim -i\alpha_p/(W_p-W_q{}^{(0)}). \tag{24.3}$$

Thus in the case of well-separated levels, when

$$|W_p-W_q{}^{(0)}|\gg\alpha_p, \tag{24.4}$$

the $c_q{}^p$ and, consequently, the imaginary part of $\Phi^{(p)}$ are small, and the latter is of the order of the ratio of the width to the spacing of the levels. Hence, to a good approximation, the energy dependence of the various parameters and the imaginary parts of the widths are absent in the region of well-separated resonances, so that, except for effects especially sensitive to these features such as the "Thomas Shift," one can usually ignore them.

The arguments in the next section do not neglect the energy dependence or the imaginary parts of the widths; these are included correctly, although we may often use the case of well-separated levels, which is especially simple, as an illustration. These features do not essentially complicate the arguments.

III. THE OPTICAL MODEL AND DIRECT INTERACTION

1. The Physical Picture

The physical picture underlying the optical model was developed chiefly by Feshbach, Porter, and Weisskopf[9]

[19] A. M. Lane (private communication).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and Friedman and Weisskopf.[20] These authors split the scattering amplitude S_α into

$$S_\alpha=\langle S_\alpha\rangle_{Av}+(S_\alpha-\langle S_\alpha\rangle_{Av}), \tag{25}$$

where $\langle S_\alpha\rangle_{Av}$ is the value of S_α averaged over an energy interval I. The averaging process is defined more precisely later. The average elastic cross section can now be expressed as

$$\langle\sigma_\alpha\rangle_{Av}=|\langle S_\alpha\rangle_{Av}|^2+\langle|S_\alpha-\langle S_\alpha\rangle_{Av}|^2\rangle_{Av}, \tag{26}$$

since the cross term between $\langle S_\alpha\rangle_{Av}$ and $S_\alpha-\langle S_\alpha\rangle_{Av}$ averages out. Although both terms on the right-hand side represent elastic scattering, they are physically quite different in nature.

Friedman and Weisskopf,[20] who used a time-dependent treatment, showed that if one constructs a wave packet of width ΔE in energy, then the scattered particles corresponding to the average amplitude $\langle S_\alpha\rangle_{Av}$, i.e., those given by the first term on the right-hand side of Eq. (26), pass over the nucleus in time $\tau=\hbar/\Delta E=\hbar/I$. This is, in fact, clearly allowed by the uncertainty principle, because one has, by averaging, constructed a scattering amplitude $\langle S_\alpha\rangle_{Av}$ which varies appreciably only over an energy interval I; since the energy of particles associated with this scattering is undefined within this interval, the time τ which the particle spends in the nucleus can be defined to within $\hbar/I$. Hence, if the energy interval I is very large, the particles corresponding to the average amplitude go over the nucleus very quickly. It is therefore reasonable that for sufficiently large intervals I, the particles make only a few interactions with the nuclear particles—even though the nucleon-nucleon potentials are relatively strong—and that we can describe them in the weak-coupling type picture indicated by the optical model. This scattering, which corresponds to the average phase, is termed "shape-elastic." Later we find precisely how large the interval I must be for various weak-coupling type descriptions of the average scattering to be valid.

On the other hand, the fluctuation scattering (often called compound-elastic scattering), described by the second term on the right-hand side of Eq. (26), varies over energy intervals of the order of the width of the compound nuclear states ($\sim$1 ev at low energies). Hence, the corresponding particles stay in the nucleus the order of a million times longer than those of the shape-elastic scattering that would correspond to a wave packet of the order of 1 Mev wide. If the particles corresponding to the shape-elastic scattering have time for one or two collisions, then those corresponding to the fluctuation scattering stay in the nucleus long enough to make the order of a million collisions. The latter particles can be regarded as those forming compound states of the type envisaged in the old compound-nucleus picture, whereas the shape-elastic scattering corresponds to that from the complex well, the imaginary part of which describes the disappearance of particles out of the incident beam into the long-lived component.

We define the complex well $\tilde{V}(r)$ so that it reproduces the average scattering phase, i.e., so that $\tilde{S}_\alpha=\langle S_\alpha\rangle_{Av}$. The physical picture indicates that this is the most reasonable procedure. We then go on to discuss the characteristics of this well $\tilde{V}(r)$ and relate the parameters back to nucleon-nucleon forces.

2. The Picture of Lane, Thomas, and Wigner

Possibly the most striking feature of experimental data on elastic neutron scattering was the appearance of the giant resonances in the total cross section in the energy region $\sim$0 to 3 Mev, as discussed in Sec. I. In order to understand these, we develop the picture of Lane, Thomas, and Wigner.[21] In this development we assume that the well $\tilde{V}(r)$, which reproduces the average scattering amplitude ($\tilde{S}_\alpha=\langle S_\alpha\rangle_{Av}$), has the characteristics of the optical model potential of Feshbach, Porter, and Weisskopf[9]; that is, if $\tilde{V}=-U-iW$ then $U\cong 42$ Mev, W lies in the range 1 to 2 Mev, and the radius of the potential is $R\cong 1.45\,A^{\frac{1}{3}}\times 10^{-13}$ cm. These parameters are used only for order-of-magnitude estimates; knowledge of their precise values is not necessary for understanding the conceptual points considered here. Later in this section we show how to relate these parameters back to nucleon-nucleon forces.

In the picture by Lane, Thomas, and Wigner,[21] for $W_p\cong\epsilon_n$, i.e., for energies of the compound states in the neighborhood of the single-particle energy ϵ_n, only terms $m=m'=n$ in the width γ_p of Eq. (17.1) are important, i.e., only the $(a_{on}{}^p)^2$ are large if W_p lies in the neighborhood of ϵ_n. We now make these criteria more quantitative. For simplicity, we consider the scattering of S-wave neutrons in the region of well-separated levels where the γ_p can be taken to be real.

We write the amplitude for compound-elastic scattering, defined by

$$S_\alpha{}^{ce}\equiv S_\alpha-\langle S_\alpha\rangle_{Av}, \tag{27}$$

in dispersion theory, using the fact that we choose $\tilde{V}$ so that $\tilde{S}_\alpha=\langle S_\alpha\rangle_{Av}$. Then,

$$S_\alpha{}^{ce}=S_\alpha-\tilde{S}_\alpha=\frac{e^{-2ikR}}{2k}\left\{\sum_p\frac{\gamma_p}{W_p-E}-\sum_m\frac{\Gamma_m}{\tilde{E}_m-E}\right\}, \tag{27.1}$$

where the second term in brackets gives the scattering amplitude in the complex well, and $\tilde{E}_m$ is the eigenvalue in the complex well, which may be taken to have the form, Eq. (9.13), $\tilde{E}_m=\epsilon_m-i\beta_m/2-iW$. (We are considering the complex well to be a square well here, although generalization to the case where it varies with r is easy.) From our definition, $\langle S_\alpha{}^{ce}\rangle_{Av}$, the average of

[20] F. L. Friedman and V. F. Weisskopf, *Niels Bohr and the Development of Physics* (Pergamon Press, London, 1955), p. 134.

[21] Lane, Thomas, and Wigner, Phys. Rev. **98**, 693 (1955).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

S^{ce}, is zero. Hence, the average of the quantity in brackets must vanish.[22] The intervals over which we average are always small compared with the widths of the single-particle resonances, so the second term in brackets need not be averaged. We can write

$$\left\{\sum_p \frac{\gamma_p}{W_p-E}\right\}_{\text{Av}} = P(E)+iQ(E) = \sum_m \frac{\Gamma_m}{\tilde{E}_m-E}, \quad (28)$$

where P and Q are real. We find

$$P(E)=\sum_m \frac{(\epsilon_m-E)\Gamma_m}{(\epsilon_m-E)^2+(W+\beta_m/2)^2}, \quad (28.1)$$

and

$$Q(E)=\sum_m \frac{\Gamma_m(W+\beta_m/2)}{(\epsilon_m-E)^2+(W+\beta_m/2)^2},$$

where Γ_m is assumed to be real, which implies specialization to the low-energy region. We cannot express $P(E)$ more simply in terms of γ_p, but the imaginary part of the sum $Q(E)$ can be put into a more useful form.

The average $\langle F(E)\rangle_{\text{Av}}$ of a quantity $F(E)$ is defined by

$$\langle F(E)\rangle_{\text{Av}} = \int_{-\infty}^{\infty} \rho(E-E')F(E')dE'. \quad (29)$$

The weighting function ρ employed by Feshbach, Porter, and Weisskopf[9] was a square one,

$$\rho(x)=\begin{cases}0, & x<-I/2\\ 1/I, & -I/2<x<I/2,\\ 0, & x>I/2\end{cases} \quad (29.1)$$

so that

$$\langle F(E)\rangle_{\text{Av}} = \frac{1}{I}\int_{E-I/2}^{E+I/2} F(E')dE'.$$

With such integrals, one has end effects coming from resonances where ϵ_p lies near either $E-I/2$ or $E+I/2$, and these must be disposed of, somewhat inelegantly. Physical results must be independent of the precise form of weighting function employed, as long as it is not an unreasonable one, and we find it convenient to use

$$\rho(E-E')=\frac{I}{\pi}\frac{1}{(E-E')^2+I^2},$$

in which case

$$\left\{\sum_p \frac{\gamma_p}{W_p-E}\right\}_{\text{Av}} = \frac{I}{\pi}\int_{-\infty}^{\infty}\sum_p \frac{\gamma_p}{W_p-E'}\frac{1}{(E-E')^2+I^2}dE'$$

$$=\sum_p \frac{\gamma_p}{W_p-E-iI}, \quad (30)$$

where the integral can be evaluated by contour integration. Quite generally, averaging with this weighting function a quantity $F(E)$ which has poles only in the lower half of the complex E plane (such functions are often called R functions following Wigner), one finds

$$\langle F(E)\rangle_{\text{Av}} = F(E+iI), \quad (31)$$

where I corresponds to the interval over which the average is carried out. We always assume this interva to contain many resonances p.

We find, then,

$$Q(E)=\text{Im}\sum_p \frac{\gamma_p}{W_p-E-iI}. \quad (32)$$

By defining the average density of the levels in the region of interest by $1/D$ (where $1/D=N$ gives the number of levels per unit energy, which is assumed to be large), one can convert the sum in Eq. (32) into an integral, obtaining

$$Q(E)=\frac{1}{D}\int_{-\infty}^{\infty}\frac{\bar{\gamma}I}{(\epsilon_p-E)^2+I^2}d\epsilon_p=\frac{\pi\bar{\gamma}}{D}, \quad (32.1)$$

where we have neglected α_p compared with I, and where $\bar{\gamma}$ is the average width. The function $\pi\bar{\gamma}/D$ is called the "strength function." Our assumption of well-separated levels is equivalent to $\pi\bar{\gamma}/D\ll 1$.

Finally, we find

$$\pi\frac{\bar{\gamma}}{D}=\text{Im}\sum_m \frac{\Gamma_m}{\tilde{E}_m-E}, \quad (32.2)$$

when we make the average value of the imaginary part of the quantity in brackets, Eq. (27.1), vanish, using $\langle S^{ce}\rangle_{\text{Av}}=0$. In the special case where the energy E is in the neighborhood of ϵ_n, the main contribution to the sum on the right-hand side comes from the nth term provided that the single-particle resonances are sufficiently far apart. Then,

$$\pi\frac{\bar{\gamma}}{D}\cong\frac{\Gamma_n(W+\beta_n/2)}{(\epsilon_n-E)^2+(W+\beta_n/2)^2}, \quad E\cong\epsilon_n. \quad (33)$$

The strength function, for constant W, Γ_n, and β_n, is thus of the Lorentz form. The contribution of the other levels is at least of order $W/\Delta\epsilon$ smaller,[23] where $\Delta\epsilon$ is

[22] In the low-energy region, where the k-dependent factor $k^{-1}\exp(-2ikR)$ and the penetrabilities in the widths vary rapidly with bombarding energy, these factors should be divided out before the average is taken. This is done explicitly in the next section.

[23] Since the sum in Eq. (32.2) relates only to the single-particle well, one can carry out the calculation of the sum explicity for special cases, such as a square well, and verify that if $\epsilon\cong\epsilon_n$, the sum of terms $m\neq n$, contributes in order $W/\Delta\epsilon$ (see Appendix A, reference 16).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the distance between single-particle levels of the *same angular momentum*, i.e., of the same channel α. This distance is of the order of U, the real part of $\tilde{V}$.

The validity of the picture depends on $W \ll U$, which is also one of the criteria for the existence of marked resonances in $\tilde{V}$. In the range of separated compound-nucleus resonances, the condition $kR \ll 1$ is fulfilled, as appears later, and then the maxima in the strength function of resonance shape given by Eq. (33) are simply related to the total cross section σ_T, as can be seen by using the optical relation

$$\sigma_T = (4\pi/k)\ \mathrm{Im}\ S_\alpha. \tag{34}$$

Hence

$$\langle \sigma_T \rangle_{Av} = \frac{4\pi}{k}\ \mathrm{Im}\langle S_\alpha \rangle_{Av} = \frac{4\pi}{k}\ \mathrm{Im}\ \tilde{S}_\alpha \cong \frac{2\pi}{k^2}\pi\frac{\bar{\gamma}}{D}, \tag{34.1}$$

which we have obtained from Eq. (32.2).

This situation just discussed is illustrated in Fig. 6, where the distance between levels $\epsilon_{n'} - \epsilon_n$ is assumed to be much greater than W, so that the picture of Lane, Thomas, and Wigner is valid. The $4s$ and $5s$ single-particle levels are shown on the left-hand side, and it is illustrated on the right-hand side how—although each single-particle level is split up into many compound states—there is an appreciable probability of finding them only within an energy region of width $\sim W$ bracketing the single-particle energy.[24] Hence, although the interaction $V(\mathbf{r},\xi)$ is strong enough to change the wave function completely so as to split the single particle level $\tilde{\psi}_n$ into thousands or millions of compound states, it is not strong enough to mix the single-particle level $\tilde{\psi}_{n'}$, which is a distance of order $\epsilon_{n'} - \epsilon_n$ away, into the compound state in the neighborhood of ϵ_n with appreciable probability.

We might ask how well the condition $(\epsilon_{n'} - \epsilon_n) \gg W$ is fulfilled in the actual physical case, taking the parameters of Feshbach, Porter, and Weisskopf[9] for $\tilde{V}$.

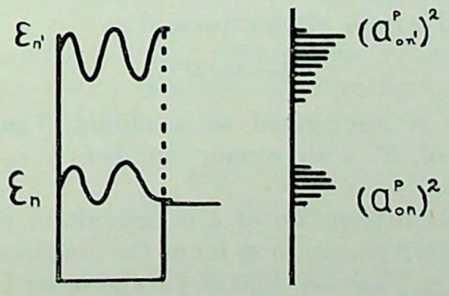

FIG. 6. On the left, S-wave single-particle resonances in the complex well are shown; on the right, the behavior of the square of the expansion coefficients. Behavior of the strength function is essentially the same as this.

By way of example, consider the nucleus A = 160 where the $4s$ single-particle resonance occurs near zero energy experimentally, as in Fig. 6. The occurrence of the $4s$ resonance requires $K_n R = (7/2)\pi$, where K_n is the wave number for a particle of zero energy, measured from the bottom of the well. The $5s$ resonance occurs for $K_{n'} R = (9/2)\pi$. Hence, $\epsilon_{n'}/\epsilon_n = 81/49$, where ϵ_n and $\epsilon_{n'}$ are now measured from the bottom of the well. For a well depth of 42 Mev, $\epsilon_{n'} - \epsilon_n \equiv \Delta\epsilon = 27$ Mev. Thus there is no doubt that $W \ll \Delta\epsilon$ is the low-energy region, where W is of order 1–2 Mev.[25]

Although the single-particle width Γ_n is split up among thousands or millions of compound states, some features of the single-particle resonance remain. In particular, since to a very good approximation,

$$\gamma_p \cong (a_{on}{}^p)^2 \Gamma_n, \quad E \cong \epsilon_n,$$

and since it follows from the completeness of our two representations connected by the coefficients $a_{jm}{}^p$ that $\sum_p (a_{on}{}^p)^2 = 1$, then

$$\sum_p{}' \gamma_p \cong \Gamma_n,$$

where the prime on the sum indicates that it is extended only over compound states in the neighborhood of ϵ_n. In other words, the single-particle width is split up among many levels, but the sum of widths of these many levels is just equal to the single-particle width.

At this stage we have an understanding of why the compound resonances p are so narrow without resorting to the classical picture which explains this in terms of the energy being shared among all of the nucleons. The interaction $V(\mathbf{r},\xi)$ is sufficiently strong so as to mix many states $\chi_j(\xi)\tilde{\psi}_m{}^j(\mathbf{r})$ into the state $\Phi^{(p)}$. Since

$$\sum_{j,m} (a_{jm}{}^p)^2 = 1,$$

following from the normalization of the $\Phi^{(p)}$, and since there are many terms which contribute in this sum, then $(a_{on}{}^p)^2 \ll 1$ for any given p and the width of the compound resonance is much less than that of the single-particle one.

Nonetheless, the interaction $V(\mathbf{r},\xi)$ is not strong enough to break down the underlying single-particle structure completely and, in particular, it does not mix different single-particle levels n and n' into the same $\Phi^{(p)}$, but only spreads the single-particle resonance locally. Consequently, it is not surprising that some of the single-particle features remain in experiments carried out with wide beams.

For completeness, we remark that the width of the strength function is given essentially by W as shown

[24] We have made arguments only for the case of separated levels where the $a_{on}{}^p$ are essentially real, and therefore our arguments do not apply in detail to the higher single-particle resonance n'. However, it is clear from them that the $(a_{on'}{}^p)^2$ has a spread of order W, where W is the imaginary part of $\tilde{V}$ (which is velocity-dependent) at the excitation energy $\epsilon_{n'}$.

[25] The discussion of the contribution of terms $m \neq n$ in Eq. (32.2) was carried out taking the same W for all terms m, contrary to the spirit of the other development where we think of $\tilde{V}$ as a velocity-dependent potential, or, equivalently, a nonlocal potential $\tilde{V}(\mathbf{r}',\mathbf{r})$, in which case the W's entering into the widths of different single-particle levels are quite different. However, the sum of terms $m \neq n$ must be the same in either method.

in Eq. (33) (although this equation is a reasonable approximation only when E is in the neighborhood of ϵ_n), and not by the square root of the second moment of the perturbing potential, as Lane, Thomas, and Wigner[21] indicated might be the case. Bloch[26] has pointed out, using some rough quantitative estimates, that one should expect the root-mean-square moment to be much larger than the width owing to large contributions from the wings of the strength function which are weighted heavily. Use of the form Eq. (33) for all energies would lead to an infinite second moment which would contradict the finite expression for it in terms of the potential,[27] so that this form is clearly not valid far from the resonance energy.

3. Low-Energy Behavior of the Scattering[28]

At low energies, where $(\pi\bar{\gamma}/D)\ll 1$ and $kR\ll 1$, the interpretation of average quantities is especially simple. Equation (34.1) shows that the average cross section is proportional to the strength function in this region. The maxima in the strength function indicated by Eq. (33) would be difficult to observe experimentally by measuring the strength function at various energies for a given nucleus because the single-particle resonance is broad, of width $2W+\beta_n$, and even if the same experimental technique could be used over this broad energy interval, the interpretation would become difficult, both because waves of higher angular momenta would be mixed into the experiments and because our simple consideration—which applied only to the region of well-separated resonances where $kR\ll 1$—would no longer be valid. Consequently, the strength function is usually measured at low energies for different nuclei and plotted as a function of A. In this way a variation in the quantity $E-\epsilon_n$ is obtained which depends on KR, where K is the wave number measured from the bottom of the well. Some experimental data, plotted in this way, are shown in Fig. 7.[29] The theoretical curve is not computed here from dispersion formalism but is obtained from

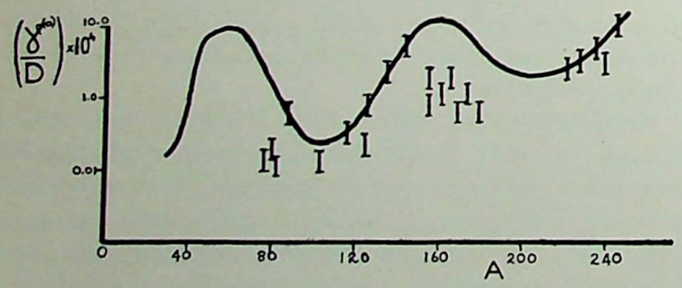

FIG. 7. Experimental data for the strength function. The solid line indicates typical theoretical predictions for a complex-well model. A measured width γ_p is reduced to a $\gamma^{(0)}$ by using $\gamma^{(0)}=\gamma_p(k_0/k)$, where k_0 is taken to be the wave number for a neutron of energy 1 ev. A more refined theory[29] takes into account nuclear deformation, and the resulting agreement between theory and experiment is then better.

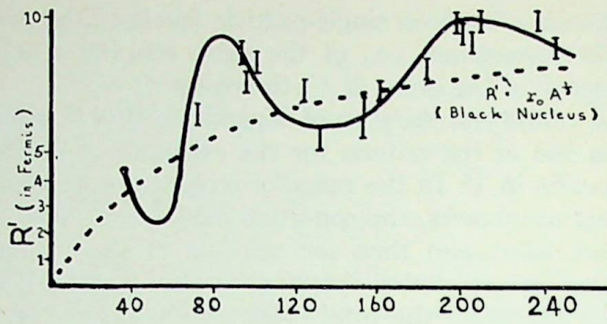

FIG. 8. Experimental data compared with theoretical predictions for R' (solid line) from the complex-well model. A more refined theory[31] takes into account nuclear deformations, and the resulting agreement between theory and experiment is then better.

$$\pi\frac{\bar{\gamma}}{D}=2k\ \mathrm{Im}\ \tilde{S}_\alpha, \tag{34.2}$$

[see Eq. (34.1)], where $\tilde{S}_\alpha$ is calculated directly by integrating the Schrödinger equation with potential $\tilde{V}$. Nevertheless, our formulas are useful in understanding the qualitative behavior in the resonance region.

Historically the first striking observations of the nonmonotonic behavior of average cross sections with changing A referred to measurement[30] of a quantity sometimes called the "potential scattering." To obtain this quantity, we expand in k, considering k to be small, but must carry the expansion one step further, i.e., we express the average cross section $\langle\sigma_T\rangle_{\mathrm{Av}}$ as

$$\langle\sigma_T\rangle_{\mathrm{Av}}=(a/k)+b, \tag{35}$$

which can be done at low energies where terms of higher order in k are negligible. The first term on the right-hand side is the familiar $1/v$ term in the cross section which is related to the strength function and which was already discussed in Eqs. (34.1) and (34.2), and the second term is often expressed as

$$b=4\pi(R')^2, \tag{35.1}$$

where R' is interpreted as a radius. The observed behavior of R' with atomic number A is shown in Fig. 8.[31]

A simple description of b is difficult to give in the Kapur-Peierls theory in so far as the imaginary parts of the width γ_p [see Eq. (23) ff.] are of order k compared with the real parts, and these must therefore be taken into account. It is consequently more straightforward to give this description in the Wigner-Eisenbud for-

[26] C. Bloch, Nuclear Phys. 3, 137 (1957).
[27] The second moment is clearly finite for well-behaved potentials which are used here.
[28] Many of the results in this section were first derived in the R-matrix formalism by R. G. Thomas, Phys. Rev. 97, 224 (1955).

malism. We sketch this briefly, following the treatment of Lane and Lynn,[32] and refer to the review article of Lane and Thomas[1] for a detailed discussion.

The expansion is actually in powers of $\rho=kR$, as in Eq. (9.5) ff., because ρ is a good expansion parameter at the energies of interest. To make this explicit, we write

$$2ik\langle S\rangle_{Av}=e^{-2i\rho}-1+2i\rho e^{-2i\rho}\langle R_{KP}\rangle_{Av}, \tag{36}$$

where

$$R_{KP}=\sum_p \chi_p/(W_p-E), \tag{36.1}$$

R_{KP} being the Kapur-Peierls R function. (It has poles only in the lower half of the complex plane.) χ_p is the reduced width,

$$\chi_p=(2\rho)^{-1}\gamma_p. \tag{36.2}$$

The relation between R_{KP} and the Wigner R function R_W is easily obtained by looking at the scattering matrix in the two theories. It is

$$R_{KP}=R_W/(1-i\rho R_W). \tag{37}$$

In averaging R_{KP} by adding iI to E, we find that

$$\langle R_{KP}\rangle_{Av}=\bar{R}_W/(1-i\rho\bar{R}_W), \tag{37.1}$$

(see pp. 306–309 of Lane and Thomas), where

$$\bar{R}_W=R_W{}^{\infty}+i\pi s_W \tag{37.2}$$

with $R_W{}^{\infty}$ and s_W now real, and given by

$$s_W=\frac{\bar{\chi}^{(0)}}{D}, \quad R_W{}^{\infty}=\int\frac{s_W(E')}{E'-E}dE'. \tag{37.3}$$

Here $\bar{\chi}^{(0)}$ is the average of $\chi_p{}^{(0)}$, the width with the Wigner-Eisenbud boundary conditions [see Eq. (23)]. The expansion to any required order is now easily made.

$$\frac{4\pi}{k}\,\mathrm{Im}\langle S_\alpha\rangle_{Av}=\frac{4\pi\rho}{k^2}(\pi s_W)+\frac{4\pi\rho^2}{k^2}\left[(1-R_W{}^{\infty})^2-(\pi s_W)^2\right]+O(\rho^3). \tag{38}$$

The left-hand side of Eq. (38) is equal to $\langle\sigma_T\rangle_{Av}$ by the relation Eq. (34.1). We now can identify easily the a and b of Eq. (35); thus,

$$a=\frac{4\pi\rho}{k^2}(\pi s_W),$$

and

$$b=4\pi\rho^2[(1-R_W{}^{\infty})^2-(\pi s_W)^2]. \tag{38.1}$$

To lowest order in ρ, $2\rho\pi s_W=\pi\bar{\gamma}/D$ and, retaining only a, we see that Eq. (38) reduces to our earlier expression, Eq. (34.1).

This derivation is independent of any particular model, although the model introduced in the last section is helpful in understanding the qualitative behavior of s_W and $R_W{}^{\infty}$ in the actual physical case. We have already indicated the resonance-type behavior in the strength function in Eq. (33). We see immediately from Eq. (37.3) that to the extent that the strength function is symmetrical about its maximum, $R_W{}^{\infty}$ is zero at this maximum which occurs at the real part of the single-particle resonance energy. Further, $R_W{}^{\infty}$ becomes negative on one side of the maximum and positive on the other so that one can understand the qualitative behavior of R' shown in Fig. 8.

Theoretical curves, such as those shown by the solid lines in Figs. 7 and 8, are obtained by calculating $\tilde{S}_\alpha$ and then using $\langle S_\alpha\rangle_{Av}=\tilde{S}_\alpha$.

In past work the term $(\pi s_W)^2$ has often been neglected. However, near the single-particle resonance at A = 50, s_W is appreciable, as R. K. Seth has pointed out,[33] and it is vital to include the term $(\pi s_W)^2$ in analyzing data near A = 50. Otherwise $(1-R_W{}^{\infty})$ comes out to be too large.

This treatment illustrates the type of problem in which the Wigner-Eisenbud formalism is useful. It is advantageous here to deal with the real quantities of this theory in which the energy dependence is explicit.

Reverting to the Kapur-Peierls formalism, we can show the relation between the average cross section for forming a compound nucleus and the W in this energy region, to lowest order in k. The former is defined as

$$\langle\sigma_c\rangle_{Av}\equiv\langle\sigma_T\rangle_{Av}-\sigma_{se},$$

where σ_{se} is the cross section for shape-elastic scattering,

$$\sigma_{se}=4\pi|\langle S_\alpha\rangle_{Av}|^2=4\pi|\tilde{S}_\alpha|^2.$$

Use of the relation between $\langle\sigma_T\rangle_{Av}$ and Im $\tilde{S}_\alpha$ given in Eq. (34.1) results in

$$\langle\sigma_c\rangle_{Av}=4\pi\left\{\frac{1}{k}\,\mathrm{Im}\,\tilde{S}_\alpha-|\tilde{S}_\alpha|^2\right\}. \tag{38.2}$$

By using the resonance expansion for $\tilde{S}_\alpha$ [obtained from Eq. (7) by replacing E_m by $\bar{E}_m$] and remembering that Γ_n is of order kR, we find, to lowest order in kR,

$$\langle\sigma_c\rangle_{Av}\cong\frac{4\pi}{k^2}\sum_m\frac{W\Gamma_m/2}{(E-\epsilon_m)^2+W^2}, \tag{38.3}$$

where we see that the shape-elastic scattering does not contribute in this order. To interpret this formula we consider $\psi_\alpha(\mathbf{r})$, the solution of the Schrödinger equation in the complex well. Since we are dealing with S waves we can expand ϕ_α, the radial part of ψ_α multiplied by r, in terms of eigenstates $\tilde{\phi}_m$. The coefficient has already been derived in Eq. (4.3). Thus

$$\phi_\alpha=\frac{h^2}{2M}e^{-ikR}\sum_m\frac{\tilde{\phi}_m(R)\tilde{\phi}_m(r)}{\bar{E}_m-E}. \tag{38.4}$$

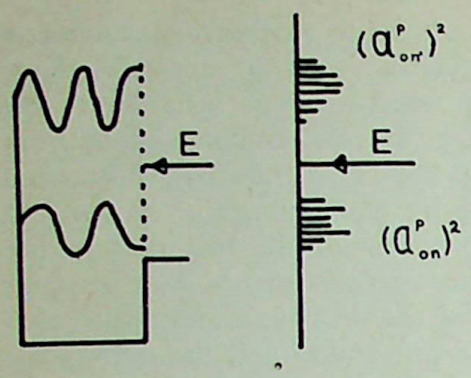

FIG. 9. Illustration of the position of the neutron energy with respect to the single-particle resonances in our "simple case of scattering."

This formula clearly shows the resonance behavior of the probability

$$\mathcal{P}_\alpha \equiv \int_0^R |\phi_\alpha(r)|^2 dr = \left(\frac{\hbar^2}{2M}\right)^2 \sum_m \frac{[\tilde{\phi}_m(R)]^2}{(E-\epsilon_m)^2+W^2}, \tag{39}$$

of finding a particle inside the nucleus whose wave function has unit amplitude asymptotically. Here we have dropped β_m which is of order kR smaller than W. It is clear that

$$\langle \sigma_c \rangle_{\text{Av}} = \frac{8\pi M}{\hbar^2 k} \mathcal{P}_\alpha W. \tag{40}$$

In other words, the average cross section for compound-nucleus formation just defined is proportional to the absorption W times the probability $\mathcal{P}_\alpha$ of finding the nucleon inside the nucleus. In a somewhat classical way, one might interpret W as the absorption per unit nucleon in the nucleus.

4. A Simple Case of Scattering

Much of the relationship of our detailed picture, where we make a complete description in terms of the $\Phi^{(p)}$ to the simplified complex-well model, can be understood by considering an especially simple case[34,35] in which the energy of the incident particle falls between single-particle resonance energies. Let us suppose, referring to Fig. 6, that the energy E of the incident particle lies midway between ϵ_n and $\epsilon_{n'}$, as in Fig. 9. The amplitude for elastic scattering coming from the lower group of levels is

$$(S_\alpha)_n = \frac{e^{-2ikR}}{2k} \sum_p \frac{(a_{on}{}^p)^2 \Gamma_n}{W_p - E} - \frac{\sin kR}{k} e^{-ikR}, \tag{41}$$

where the lower suffix n on S_α indicates that this is the S_α that would result if only the lower group of levels existed. We have here used the model developed in the last section and dropped the $a_{on'}{}^p$ in the widths γ_p referring to the set of compound-nucleus levels lying around ϵ_n.

The W_p are spread a distance W about ϵ_n. Consequently, if $E-\epsilon_n \gg W$, then a good first approximation is to set $E-W_p$ equal to $E-\epsilon_n$ in the denominator of Eq. (41). Evaluation of the sum over p gives in this approximation,

$$(S_\alpha)_n = \frac{e^{-2ikR}}{2k} \frac{\Gamma_n}{\epsilon_n - E} - \frac{\sin kR}{k} e^{-ikR}, \tag{42}$$

which is just the contribution to S_α from the nth resonance in the complex-well picture if we neglect W compared with $E-\epsilon_n$ in the denominator.

Therefore, if the spread of the γ_p about the single-particle resonance energy is small, then the whole set of them act together just as the single-particle resonance. This is related to the principle of spectroscopic stability, from which it follows that—although the wave functions may be drastically changed by the perturbation—certain simple features come out just as in the unperturbed problem.

The main oversimplification is in the neglect of the widths γ_p which lie close to E, i.e., the γ_p are not so well concentrated around ϵ_n and $\epsilon_{n'}$ as we have shown. However, our approximations are good in so far as the "shape-elastic" scattering is concerned. Our neglect of the near levels has simply resulted in our dropping the compound-elastic scattering. We now make the development more precise in such a way that the near levels can also be treated. Such a treatment is clearly necessary in order to consider general E which may be in the region of a single-particle resonance.

5. Expression of the Scattering in the Green's Function Formalism

In defining $\tilde{V}(r)$, it is convenient to express S^{ce} in terms of the Green's function as was done by Bloch.[36] Actually, Bloch's elegant formalism is much more general than that we use, and by specialization to specific representations he can obtain either the Kapur-Peierls or Wigner-Eisenbud expression. However, our simpler formalism is adequate for illustrating the points considered here. We again specialize our consideration to the scattering of S-wave neutrons; generalization of our results to other cases is obvious.

We use the notation

$$\Phi^{(p)}(\mathbf{r},\xi) = |p\rangle = \langle p|, \quad \chi_j(\xi)\tilde{\psi}_m{}^j(\mathbf{r}) = |jm\rangle = \langle jm|, \tag{43}$$

and

$$\langle p|jm\rangle = \int_0^R \Phi^{(p)}(\mathbf{r},\xi)\chi_j(\xi)\tilde{\psi}_m{}^j(\mathbf{r}) d^3r d^3\xi = a_{jm}{}^p.$$

No distinction is made between $|p\rangle$ and $\langle p|$ since expansion and orthogonality conditions in this theory involve only the wave function and not its complex conjugate, aside from the trivial changes in functions of angles mentioned in part 2 of this section.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

We then have

$$S_\alpha{}^{ce}=\frac{e^{-2ikR}}{2k}\left\{\sum_p\frac{\gamma_p}{W_p-E}-\sum_m\frac{\Gamma_m}{\tilde{E}_m-E}\right\},$$

$$=\frac{h^2}{2M}e^{-2ikR}\sum_{m,m'}\left\{\sum_p\langle p|\,om\rangle\langle p|\,om'\rangle\left\langle p\left|\frac{1}{H-E}\right|p\right\rangle\right.$$

$$\left.-\left\langle om\left|\frac{1}{\tilde{H}-E}\right|om'\right\rangle\right\}\tilde{\phi}_m(R)\tilde{\phi}_{m'}(R), \quad (44)$$

$$=\frac{h^2}{2M}e^{-2ikR}\sum_{m,m'}\left\{\left\langle om\left|\frac{1}{H-E}\right|om'\right\rangle\right.$$

$$\left.-\left\langle om\left|\frac{1}{\tilde{H}-E}\right|om'\right\rangle\right\}\tilde{\phi}_m(R)\tilde{\phi}_{m'}(R),$$

where $\tilde{H}$ is obtained from H by replacing $V(\mathbf{r},\xi)$ by $\tilde{V}$, i.e.,

$$H=\tilde{H}+(V(\mathbf{r},\xi)-\tilde{V}(r))=\tilde{H}+\delta V. \quad (44.1)$$

By using the identity

$$\frac{1}{H-E}=\frac{1}{\tilde{H}-E}-\frac{1}{\tilde{H}-E}(V-\tilde{V})\frac{1}{\tilde{H}-E}$$

$$+\frac{1}{\tilde{H}-E}(V-\tilde{V})\frac{1}{H-E}(V-\tilde{V})\frac{1}{\tilde{H}-E}, \quad (45)$$

which is easily checked by multiplying both sides of the equation by $H-E$, we obtain

$$S_\alpha{}^{ce}=-\frac{h^2}{2M}e^{-2ikR}\sum_{m,m'}\frac{1}{\tilde{E}_m-E}\frac{1}{\tilde{E}_{m'}-E}$$

$$\times\left\{\langle om|\,V-\tilde{V}|\,om'\rangle-\left\langle om\left|(V-\tilde{V})\frac{1}{H-E}\right.\right.\right.$$

$$\left.\left.\left.\times(V-\tilde{V})\right|om'\right\rangle\right\}\tilde{\phi}_m(R)\tilde{\phi}_{m'}(R). \quad (46)$$

At this stage, by using Eq. (38.4) we obtain $S_\alpha{}^{ce}$ in a convenient form,

$$S_\alpha{}^{ce}=-\frac{2M}{h^2}\left\{\langle o\alpha|\,V-\tilde{V}|\,o\alpha\rangle\right.$$

$$\left.-\left\langle o\alpha\left|(V-\tilde{V})\frac{1}{H-E}(V-\tilde{V})\right|o\alpha\right\rangle\right\}, \quad (47)$$

where ψ_α is the scattering state defined by Eq. (11) and the discussion following it. Further expansion of $1/(H-E)$ by iteration with Eq. (45) would give the Born expansion for $S_\alpha{}^{ce}$, i.e., the expansion in successive powers of the perturbing potential δV. Equation (47) can be derived directly from scattering theory without recourse to dispersion theory.

Insertion of the unit operator $\sum_p|\,p\rangle\langle p\,|$ in the second term on the right-hand sides of Eqs. (46) and (47) allows replacement of $(H-E)^{-1}$ by $(W_p-E)^{-1}$, indicating that all of the poles of this term lie in the lower half of the complex energy plane. Thus we can average this term with respect to energy by replacing E by $E+iI$, following the procedure of Eqs. (30) and (31).

$$\langle S_\alpha{}^{ce}(E)\rangle_{Av}=S_\alpha{}^{ce}(E+iI). \quad (48)$$

The complex potential $\tilde{V}(r)$ is defined by the condition $\tilde{S}_\alpha(E)=\langle S_\alpha(E)\rangle_{Av}$, or by $\langle S_\alpha{}^{ce}(E)\rangle_{Av}=0$. This can be accomplished by requiring

$$\langle o|\,V-\tilde{V}|\,o\rangle$$

$$-\left\langle o\left|(V-\tilde{V})\frac{1}{H-E-iI}(V-\tilde{V})\right|o\right\rangle=0. \quad (49)$$

One can therefore define an optical potential $\tilde{V}(r)$ which reproduces the average scattering phase. At this stage, not very much has been proved because the formalism does not make it clear that $\tilde{V}$ does not vary rapidly and possibly nonmonotonically with energy; its usefulness empirically comes from the fact that it varies slowly and regularly with energy and with atomic number A. We now go as far as we can towards demonstrating that $\tilde{V}$ has these characteristics. In order to do this, we make the connection between the parameters of $\tilde{V}$ and the nucleon-nucleon potentials.

6. Perturbation Theory of the First Kind

In the perturbation theory to be developed, we will have to carry out an expansion in $\delta V=V(\mathbf{r},\xi)-\tilde{V}(r)$ since we wish to obtain expressions for quantities which do not contain the complicated $\Phi^{(p)}$. The smallness of the widths of the $\Phi^{(p)}$ compared with those of the single-particle states $\tilde{\psi}_m$ which, together with χ_j we employ as unperturbed wave functions, indicates that a large number of terms are necessary in the expansion Eq. (14) of $\Phi^{(p)}$ in terms of $\chi_j(\xi)\tilde{\psi}_m{}^j(\mathbf{r})$. Thus, an expansion of $\Phi^{(p)}$ in perturbation theory, starting from $\chi_0(\xi)\tilde{\psi}_m{}^j(\mathbf{r})$ as zero-order function, would converge very slowly, if at all. However, the perturbation expansions of the average phase involve less stringent criteria for convergence than those for the wave functions as might be suspected from the physical arguments of the first part of this section. We now formulate these criteria, following the development of Brown, De Dominicis, and Langer.[37]

$\mathfrak{W}$ is defined as

$$\tilde{V}=\bar{V}-\mathfrak{W}, \quad (49.1)$$

where

$$\bar{V}\equiv\langle o|\,V|\,o\rangle. \quad (49.2)$$

[37] Brown, De Dominicis, and Langer, Ann. Phys. (N. Y.) **6**, 209 (1959).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Our defining equation, Eq. (49), for $\tilde{V}$ becomes

$$\left\langle o\left|(V-\bar{V}+\mathfrak{W})\left[1-\frac{1}{H-E-iI}(V-\bar{V}+\mathfrak{W})\right]\right|o\right\rangle=0. \tag{49.3}$$

Equation (49.3) can be explicitly solved for $\mathfrak{W}$.[38] For brevity,

$$e=H-E-iI, \tag{49.4}$$

and

$$\bar{e}=\bar{H}-E-iI=e-(V-\bar{V}).$$

Then Eq. (49.3) can be written

$$\begin{aligned}&\left\langle o\left|(e-\bar{e}+\mathfrak{W})\left[1-\frac{1}{e}(e-\bar{e}+\mathfrak{W})\right]\right|o\right\rangle=0,\\ &=\left\langle o\left|(e-\bar{e}+\mathfrak{W})\frac{1}{e}(\bar{e}-\mathfrak{W})\right|o\right\rangle,\\ &=\left\langle o\left|(e-\bar{e})\frac{1}{e}\bar{e}\right|o\right\rangle-\left\langle o\left|(e-\bar{e})\frac{1}{e}\right|o\right\rangle\mathfrak{W}\\ &\qquad+\mathfrak{W}\left\langle o\left|\frac{1}{e}(\bar{e}-\mathfrak{W}\right|o\right\rangle.\end{aligned} \tag{49.5}$$

Since $H_\xi|O\rangle=0$, the factor $(\bar{e}-\mathfrak{W})$ in the final term commutes with $|o\rangle$ and can be taken out to the right. Equations (45)–(49) imply

$$\left\langle o\left|\frac{1}{e}\right|o\right\rangle=\left\langle o\left|\frac{1}{\bar{e}-\mathfrak{W}}\right|o\right\rangle, \tag{49.6}$$

and from this we see that the final term in Eq. (49.5) is equal to $\mathfrak{W}$. We can then solve the equation for $\mathfrak{W}$, obtaining

$$\mathfrak{W}=\frac{1}{1-\left\langle o\left|(V-\bar{V})\frac{1}{e}\right|o\right\rangle}\left\langle o\left|(V-\bar{V})\frac{1}{e}(V-\bar{V})\right|o\right\rangle, \tag{49.7}$$

where we have added to the final factor the term

$$\left\langle o\left|(e-\bar{e})\frac{1}{e}e\right|o\right\rangle,$$

for symmetry. This term is zero, since $\langle o|e-\bar{e}|o\rangle=0$. Equation (49.7) is equivalent to

$$\mathfrak{W}=\left\langle o\left|(V-\bar{V})\frac{1}{e-\Lambda_o(V-\bar{V})}(V-\bar{V})\right|o\right\rangle, \tag{50}$$

where

$$\Lambda_o=|o\rangle\langle o|, \tag{50.1}$$

as can be checked by expanding in powers of $(V-\bar{V})1/e$. One can derive this expression without recourse to perturbation theory as an intermediate step.[39,40] For purposes of perturbation theory it is more useful to think of the denominator of Eq. (50) as $\bar{e}+(1-\Lambda_o)(V-\bar{V})$, since the expansion is in powers of $(1-\Lambda_o)(V-\bar{V})$.

In working with Eq. (50) it is advantageous to use a representation for the extra particle which is diagonal in $T+\bar{V}$ rather than in $T+\tilde{V}$. The importance of considering $\mathfrak{W}$ comes from the fact that it contains the entire imaginary part of $\tilde{V}$; its contribution to the real part of $\tilde{V}$ would be important only in case one was trying to calculate this quantity fairly accurately. For the simple case in which $\tilde{V}$ is a square well, changing the imaginary part of it by iW does not change th eeigenfunctions but only shifts the resonance energies by iW. Our new energy eigenvalues are, therefore,

$$E_m=\epsilon_m-i\beta_m/2. \tag{50.2}$$

We now investigate the eigenfunctions and eigenvalues of the operator

$$\mathfrak{H}=H-\Lambda_o(V-\bar{V}). \tag{51}$$

We label them by Ω_p and W_p', i.e.,

$$\mathfrak{H}\Omega_p=W_p'\Omega_p. \tag{51.1}$$

Now, $-\Lambda_o(V-\bar{V})$ can be considered as a small perturbation since the Ω_p are not very different from the $\Phi^{(p)}$. Thus, we choose

$$\Omega_p=\Phi^{(p)}+\delta\Omega_p, \tag{52}$$

and

$$\delta\Omega_p=\textstyle\sum_n a_p{}^n\Phi^{(n)}.$$

To lowest order

$$W_p'=W_p. \tag{52.1}$$

The use of Green's theorem as in Eq. (16) and the assumption[41] that Ω_p satisfies the same boundary condition as $\Phi^{(p)}$, gives the result

$$\begin{aligned}&\int_0^R(\Phi^{(n)}\mathfrak{H}\Omega_p-\Omega_p\mathfrak{H}\Phi^{(n)})d^3\xi d^3r=0\\ &=(W_p-W_n)a_p{}^n+\sum_m\langle p|(V-\bar{V})|om\rangle\langle om|n\rangle,\end{aligned} \tag{53}$$

where $W_p'=W_p$ and $\Omega_p=\Phi^{(p)}$ on the right-hand side since we wish to compute $a_p{}^n$ only to lowest order. By employing

$$\begin{aligned}\langle p|V-\bar{V}|om\rangle&=\langle p|H-\bar{H}|om\rangle\\ &=(W_p-\epsilon_m+i\beta_m/2)\langle p|om\rangle,\end{aligned} \tag{54}$$

[38] C. T. De Dominicis, J. phys. radium **19**, 1 (1958).

[39] J. S. Langer, thesis, University of Birmingham, 1958.

[40] H. Feshbach, Ann. Rev. Nuclear Sci. 8, 44 (1958).

[41] Actually, the functions Ω_p obey slightly different boundary conditions from the $\Phi^{(n)}$, because, as is clear from Eq. (51), the Ω_p contain no components χ_0, these being projected out by the operator Λ_0. However, such components of $\Phi^{(n)}$ do not contribute to the left-hand side of Eq. (53) because they are orthogonal to Ω_p, and the equality given there holds.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

we obtain

$$a_p{}^n=\sum_m \frac{(W_p-\epsilon_m+i\beta_m/2)}{W_n-W_p}\langle p|\,om\rangle\langle om|\,n\rangle. \quad (55)$$

For order-of-magnitude estimates,

$$\langle p|\,om\rangle\langle om|\,n\rangle\beta_m\sim\langle p|\,om\rangle^2\beta_m\sim\gamma_p,$$

and on the giant resonance

$$W_p-\epsilon_m\lesssim W.$$

As a result the $a_p{}^n$ are large only if $(W_p-W_n)\sim W\gamma_p/\Gamma_m$ and, therefore, because of the smallness of γ_p, only a few of the neighboring Φ's are mixed into each Ω by the perturbation.

We can expand the Ω's in terms of the χ's and the ψ's just as with the $\Phi^{(p)}$'s. Then

$$\Omega_p=\sum_{j,m} b_{jm}{}^p\chi_j(\xi)\bar{\psi}_m{}^j(\mathbf{r}). \quad (55.1)$$

One important difference between the right-hand side of Eq. (55.1) and that of the expansion of the $\Phi^{(p)}$, Eq. (14), is that the right-hand side of Eq. (55.1) contains no terms with $j=0$. These have been projected out by the operator Λ_o, so that the eigenfunctions of $\mathfrak{IC}$ form a complete set in the space orthogonal to χ_0.

Since the eigenvalues and eigenfunctions of $\mathfrak{IC}$ differ only slightly from those of H, aside from the fact that the former do not contain components in $|o\rangle$, our arguments about the distribution of the $a_{jm}{}^p$ apply equally well to the distribution of the $b_{jm}{}^p$. However, it is important to retain the Λ_o in the denominator of Eq. (50), i.e., not to approximate the Ω_p by the $\Phi^{(p)}$,[42] because this would allow states $|o\rangle$ to occur as intermediate states in the expansion which would give large spurious contributions. Retaining the Λ_o is related to the need to eliminate unlinked clusters in expansions of the Brueckner type.

We are now ready to discuss the criteria for perturbation theory. We can express the matrix element as

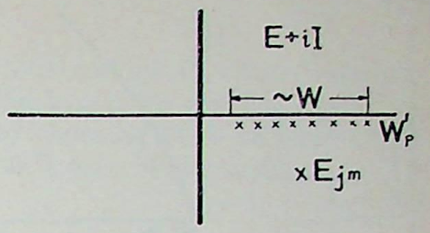
$$\langle on|\,\mathfrak{W}(E)\,|on\rangle=\langle on|\,V-\bar{V}\,|p'\rangle \times\frac{1}{W_{p'}-E-iI}\langle p'|\,V-\bar{V}\,|on\rangle, \quad (56)$$

where we label the eigenfunctions of $\mathfrak{IC}$ by $|p'\rangle$. In a perturbation expansion of the type

$$\mathfrak{W}(E)=\left\langle o\left|(V-\bar{V})\frac{1}{\bar{H}-E-iI}\sum_{n=0}^{\infty}(-1)^n \times\left[(1-\Lambda_0)(V-\bar{V})\frac{1}{\bar{H}-E-iI}\right]^n(V-\bar{V})\right|o\right\rangle, \quad (57)$$

[42] This was pointed out to the author by Dr. A. M. Lane. The partial summation of Bloch[26] takes this into account properly.

FIG. 10. Positions of poles in the complex-energy plane. The scattering amplitude, averaged over energy interval I, is obtained by taking its value for the complex energy $E+iI$.



the lowest-order term of the expansion can be expressed as

$$\langle on|\,\mathfrak{W}(E)\,|on\rangle\cong\sum_{j,m}\frac{\langle on|\,V-\bar{V}\,|jm\rangle\langle jm|\,V-\bar{V}\,|on\rangle}{E_{jm}-E-iI}. \quad (58)$$

The same result can be obtained by replacing $|p'\rangle$ by $\sum_{j,m}|\,jm\rangle\langle jm|\,p'\rangle$ in Eq. (56) and then approximating W_p' by E_{jm}. This approximation is justified if I is large, because the $\langle jm|\,p'\rangle$ are large only if $W_p'-\epsilon_{jm}\lesssim W$ by the arguments of the preceding section. The situation is illustrated in Fig. 10. In the complex energy plane, the state $|\,jm\rangle$ has an appreciable probability of being found in states $|p'\rangle$ distributed over a region of width W. In going from Eq. (56) to the approximation Eq. (58), we are approximating the distances $E+iI-W_p'$ in the energy plane by the common distance $E+iI-E_{jm}$. This is justified if $|E+iI-E_{jm}|\gg W$, W giving the spread of the W_p' as indicated in Fig. 10. In the worst case for the fulfillment of this criterion, in which $E=\epsilon_{jm}$, which is illustrated in Fig. 10, we can satisfy this criterion by making I sufficiently large, so we must have $I\gg W$.

This could be phrased in the following way: Calculating only the average phase means that we can evaluate it for the imaginary energy $\mathcal{E}=E+iI$. The approximation of taking only the first term in the expansion is clearly better, the larger $\mathcal{E}-E_{jm}$. In the simple case of scattering considered earlier (where we actually approximated at a different stage), a large value for the distance between $\mathcal{E}$ and the single-particle resonance was obtained by taking E, the real part of $\mathcal{E}$, to be far away. The same result can be achieved by pushing $\mathcal{E}$ up in the complex plane, which means averaging over larger intervals.

We have thus formulated mathematically the physical considerations of part 1 of this section. There it was seen that the time spent in the nucleus by the particles corresponding to the average phase decreased as the interval I, over which the average was carried out, increased. This development shows that the larger I is, the faster the series Eq. (57) converges. This series in powers of δV can be interpreted as an expansion in the number of collisions the incident particle makes with the target nucleons. The larger I is, the more quickly the particle passes over the nucleus and the fewer the collisions it makes.

The expansion of $\mathfrak{W}$ in this way has been carried out by Bloch.[36] After expansion, he makes assumptions

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

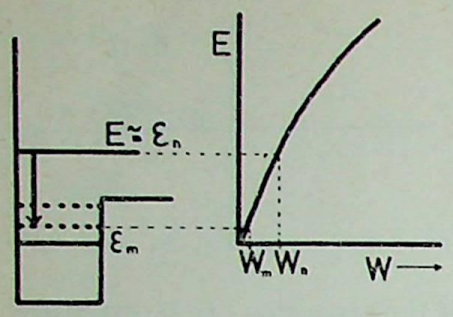


FIG. 11. Variation of absorption W with energy of the single-particle excitation.

about the randomness of signs of the $\langle kl|\delta V|jm\rangle$. We do not, however, make such assumptions, and show later that they are not justified. The expansion is, however, convergent without these assumptions provided I is sufficiently large.

It might appear that the condition $I \gg W$ is difficult to achieve. The decisive point here is that the W to be employed is the W appropriate to the state $|jm\rangle$ which corresponds to the nucleus excited by energy ϵ_j and a single particle of energy roughly $E-\epsilon_j$ in the well. This is illustrated in Fig. 11. From our earlier developments, we can assume energy conservation to within the width of the excitation $|jm\rangle$. Thus $E \cong \epsilon_j + \epsilon_m$. The width of the state $|j\rangle$, which is a true compound state, can be neglected relative to that of the single-particle excitation $|m\rangle$. But the W corresponding to state $|m\rangle$ is much smaller than that corresponding to state $|n\rangle$ because the former is far down in the well, and W is a rapidly increasing function of energy, as shown in Fig. 11. Taking the quadratic dependence of W given by simple theories, as discussed later,

$$W_m = \left(\frac{E-\epsilon_j}{E}\right)^2 W_n, \tag{59}$$

where we have put a lower suffix m on the W on the left-hand side to indicate that it refers to the state $|m\rangle$, and we now denote the W referring to state $|n\rangle$ by W_n. In other words, the width of the state into which the single-particle excitation decays is less than the width of the original single-particle excitation.

Usually, the state j is a highly excited one since the number of states per Mev available increases exponentially with excitation,[43] and in this case $W_m \ll W_n$. Of course, the more highly excited states also tend to have a more complicated structure so that the matrix elements for excitation of the A particles become smaller. In the next part of this section it is shown that the ratio $(E-\epsilon_j)/E$ tends to be $\sim 1/3$ or, $W_m/W_n \sim 1/9$. However, in the case of easily deformable nuclei, there are large matrix elements to low-lying states j, the collective ones.

From the foregoing, we see that the inequalities

$$W_m < I < W_n, \tag{60}$$

can usually be satisfied, although W_m is smaller than W_n only by a numerical factor and not by orders of magnitude. When these inequalities are satisfied, the average can be carried out over an interval which is large enough for the convergence of perturbation theory but small enough so that one can still obtain information about the shape of the single-particle resonance of width $\sim W_n$. In fact, neglect of the variation in the $|n\rangle$ and other quantities in the various averages constrains us to average over a distance $< W_n$.

The same arguments apply, with slight modification, to the case of inelastic processes going into a low-excited final state. Here the transition amplitude is

$$S_{\alpha\alpha',j} = -\frac{2M}{\hbar^2}\Big\{\langle j\alpha'|V-\tilde{V}|o\alpha\rangle - \Big\langle j\alpha'\Big|(V-\tilde{V})\frac{1}{H-E}(V-\tilde{V})\Big|o\alpha\Big\rangle\Big\},$$

$$= -\frac{\hbar^2}{2M}e^{-i(k+k_j)R}\sum_{m,m'}\frac{1}{\tilde{E}_m - E}\frac{1}{\tilde{E}_{m'}-E}$$

$$\times\Big\{\langle jm'|V-\tilde{V}|om\rangle - \Big\langle jm'\Big|(V-\tilde{V})\frac{1}{H-E}$$

$$\times(V-\tilde{V})\Big|om\Big\rangle\Big\}\tilde{\phi}_m(R)\tilde{\phi}_{m'}{}^{j}(R),$$

where j is assumed to be a low-excited state. Perturbation theory can be used to calculate the $\langle S_{\alpha\alpha',j}\rangle_{\text{Av}}$, since the states that m and m' decay into are, in general, of substantially lower energy and consequently have a smaller width. This gives the result, in the first approximation,

$$\langle S_{\alpha\alpha',j}\rangle_{\text{Av}} \cong -\frac{2M}{\hbar^2}\langle j\alpha'|V-\bar{V}|o\alpha\rangle, \tag{62}$$

which has been used extensively in calculating direct interaction processes. This is just the same result as follows from lowest-order Born approximation, i.e., keeping only the lowest term in δV with initial and final states distorted by the complex well. Such a weak interaction picture is only applicable to the average phase and then only if it is averaged over a large energy interval.

7. Perturbation Theory of the Second Kind

Relation (62) is an important one in that it justifies the use of perturbation theory—in the usual terminology, Born approximation with distorted waves—in direct interaction calculations. We found also, in part 6, that the average elastic scattering amplitude was reproduced by $\tilde{V} = \bar{V} - \mathfrak{W}$ with $\mathfrak{W}$ given to lowest order by Eq. (58). This latter relation is interesting but not well adapted for the calculation of $\mathfrak{W}$ since it still

[43] The energy of excitation is limited since the initially excited particle does not drop into a state already occupied. This is inconsistent with our neglect of antisymmetrization, but this does not seem to be an essential difficulty.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

involves the highly complicated nuclear states $\chi_j(\xi)$. We therefore develop a perturbation expansion of the type used by Bruckner, Eden, and Francis[44] which essentially relates quantities back to shell-model states. This expansion gives an expression for $\mathcal{W}$ which is practical for calculation; however, to satisfy the criterion for its validity, one must average over a large energy interval as we shall see.

In this treatment the unperturbed Hamiltonian is

$$\bar{H}=\sum_{i=0}^{A}(T_i+V_i)-\tfrac{1}{2}\sum_{i,j=0}^{A}\bar{V}_{ij}, \tag{63}$$

with eigenstates $|\bar{q}\rangle$ such that

$$\bar{H}|\bar{q}\rangle=E_{\bar{q}}|\bar{q}\rangle. \tag{63.1}$$

Here V_i is the self-consistent potential defined in the state $|\bar{q}\rangle$ felt by the ith particle, as in the Hartree-Fock theory, and

$$\bar{V}_{ij}=\langle\bar{q}|V_{ij}|\bar{q}\rangle. \tag{63.2}$$

The summations cover the incident particle ($i=0$) as well as the A particles in the nucleus. Thus, the A+1 particles are here treated symmetrically. The c number, $\frac{1}{2}\sum_{i,j}\bar{V}_{ij}$, has been subtracted to ensure that $\langle\bar{q}|H|\bar{q}\rangle$ is equal to the energy in the Hartree-Fock approximation. The crucial question in using the $|\bar{q}\rangle$ as zero-order functions relates to the extent of the spread of the strength function $\langle\bar{q}|p\rangle^2$ in energy. This can be obtained from

$$\frac{\pi}{D}\{\langle\bar{q}|p\rangle^2\}_{Av}=\mathrm{Im}\left\{\left\langle\bar{q}\left|\frac{1}{H-E}\right|\bar{q}\right\rangle\right\}_{Av}$$
$$=\mathrm{Im}\left\langle\bar{q}\left|\frac{1}{\tilde{H}-E}\right|\bar{q}\right\rangle, \tag{64}$$

where $\tilde{H}$ is a comparison Hamiltonian which has been introduced as an artifice to calculate this strength function.[45] Its significance is seen later. It is given by

$$\tilde{H}=\bar{H}-\mathcal{W}, \tag{64.1}$$

where $\mathcal{W}$ is then defined by

$$0=\left\langle\bar{q}\left|\mathcal{W}\right|\bar{q}\right\rangle$$
$$-\left\langle\bar{q}\left|(V-\bar{V}+\mathcal{W})\frac{1}{H-E-iI}(V-\bar{V}+\mathcal{W})\right|\bar{q}\right\rangle, \tag{64.2}$$

which guarantees satisfaction of Eq. (64). [See the similar development, Eqs. (44)–(49).] This equation is formally similar to Eq. (56), and by the same procedure as employed to solve the latter, we can find that Eq. (64.2) can be satisfied by choosing $\mathcal{W}$ to be diagonal in the $|\bar{q}\rangle$ representation, with matrix elements

$$\langle\bar{q}|\mathcal{W}|\bar{q}\rangle$$
$$=\left\langle\bar{q}\left|(H-\bar{H})\frac{1}{H-\Lambda_{\bar{q}}(V-\bar{V})-E-iI}(H-\bar{H})\right|\bar{q}\right\rangle, \tag{65}$$

where

$$\Lambda_{\bar{q}}=|\bar{q}\rangle\langle\bar{q}|. \tag{65.1}$$

In evaluating $\langle\bar{q}|\mathcal{W}|\bar{q}\rangle$ by lowest-order perturbation theory which now means replacing

$$\{H-\Lambda_{\bar{q}}(H-\bar{H})-E-iI\}^{-1}$$

by

$$\sum_{\bar{s}\neq\bar{q}}|\bar{s}\rangle\{E_{\bar{s}}-E-iI\}^{-1}\langle\bar{s}|,$$

we find that

$$\mathcal{W}=\sum_{i<j=0}^{A}\mathcal{W}_{ij}, \tag{65.3}$$

with

$$\langle\bar{q}|\mathcal{W}_{ij}|\bar{q}\rangle=\sum_{\bar{s}\neq\bar{q}}\langle\bar{q}|V_{ij}|\bar{s}\rangle\frac{1}{E_{\bar{s}}-E-iI}\langle\bar{s}|V_{ij}|\bar{q}\rangle. \tag{65.4}$$

The half-width of the strength function $\pi\{\langle\bar{q}|p\rangle^2\}_{Av}/D$ is given by

$$\sum_{i<j=0}^{A}\mathrm{Im}\langle\bar{q}|\mathcal{W}_{ij}|\bar{q}\rangle, \tag{65.5}$$

if we neglect the natural width of the state $|\bar{q}\rangle$.

If we identify $|\bar{q}\rangle$ with the state in which A+1 particles form a state, wherein the A levels from the bottom of the well are filled except for one hole in the state we label by k' and in which two particles are excited in states labeled by k and l, then it is easy to identify the various parts of the width:

1. $\mathrm{Im}\sum_{j=0}^{A}\langle\bar{q}|\mathcal{W}_{kj}|\bar{q}\rangle$ and $\mathrm{Im}\sum_{i=0}^{A}\langle\bar{q}|\mathcal{W}_{li}|\bar{q}\rangle$,

correspond to the widths for the particles k and l to interact with the other particles so that the two-particle excitation, in perturbation theory language, decays into a three-particle excitation. (One should omit $j=k'$ and $i=k'$ in the sums.)

2. $\mathrm{Im}\sum_{j}{}'\langle\bar{q}|\mathcal{W}_{k'j}|\bar{q}\rangle$ corresponds to the width for the decay of the shell model state with a hole in it, i.e., the width for absorption of the hole. (The prime indicates that the term $j=k'$ should be omitted. But $j=k$ and l should, for completeness, be included in the sum.)

By using the approximate symmetry of holes and particles[46] near the Fermi surface E_F, we find that the

[44] Brueckner, Eden, and Francis, Phys. Rev. **100**, 891 (1955). See also M. Cini and S. Fubini, Nuovo cimento **2**, 75 (1955) and A. M. Lane and C. F. Wandel, Phys. Rev. **98**, 1524 (1955).

[45] We use the symbols $\tilde{H}$ and $\mathcal{W}$ because, although they stand now for different quantities than previously, there is a close analogy between these and the previous ones.

[46] Calculations by E. P. Pendlebury, analogous to those of Lane and Wandel,[44] indicate that this symmetry holds only near the Fermi surface; the absorption for holes then rises more steeply than that for particles (private communication).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

total width of $|\bar{q}\rangle$ is

$$W_{\bar{q}}=W_k+W_l+W_{k'}$$

$$\cong\left\{\frac{(\epsilon_k-E_F)^2+(\epsilon_l-E_F)^2+(E_F-\epsilon_{k'})^2}{(\epsilon_n-E_F)^2}\right\}W_n, \quad (66)$$

from the simple theories referred to previously. We label the width of the original single-particle excitation $|n\rangle$ by W_n as previously, and we employ the W's to denote the imaginary parts of the $\mathcal{W}_{ij}$.

The width of our original single-particle excitation is given in the lowest approximation by

$$W_n=\mathrm{Im}\sum_{\bar{q}}$$

$$\frac{\langle on|\sum_{i=1}^{A}V_{oi}-\sum\bar{V}_{oi}|\bar{q}\rangle\langle\bar{q}|\sum V_{oi}-\sum\bar{V}_{oi}|on\rangle}{E_{\bar{q}}-E-iI}. \quad (67)$$

The largest phase space is available when the energy is equally distributed among the particles and the hole so that W_k, W_l, and $W_{k'}$ are each $\sim(1/9)W_n$. Since $W_k+W_l+W_{k'}<W$, we can again satisfy

$$W_{\bar{q}}<I<W_n, \quad (68)$$

and employ perturbation theory, although all three of these quantities are of the same order of magnitude, so that the average must be carried out over an interval I that is a good fraction of the width of the single-particle resonance.

In case $|o\rangle$ can be described as a shell-model state, i.e., as an antisymmetrized wave function of independent particles moving in a well, or can be obtained from such a state by successive application of the two-body interaction, the A+1 particles can be treated symmetrically, and the identity of the particles can be taken into account easily. By using such an iteration in which the evaluation is carried out starting from the Fermi sea, which is assumed to be a reasonable approximation for the interior of a large nucleus, Brueckner[47] finds that the value of W is increased considerably over that given by the simple theory and introduces both a term linear in energy and a constant term in the dependence of W. This would mean that the criterion, Eq. (67), might not be satisfied by any I since the sum $W_k+W_l+W_{k'}$ might be as large as W_n. Whereas Brueckner's calculation brings out the sensitivity of W to correlations in the ground-state wave function near the Fermi surface, there are good indications that these cannot be calculated in perturbation theory, i.e., that the ground-state wave function $\chi_o(\xi)$ cannot be obtained in the region of the Fermi surface by iterating the shell-model state.[48] In fact, the parts of these correlations responsible for the pairing forces tend to make the Fermi surface stiffer against perturbations, working in the opposite direction from the effects calculated by Brueckner.[47] Consequently, a consistent evaluation of the corrections to the lowest-order theory undoubtedly gives results smaller than Brueckner's calculation.

In the discussion following Eq. (59) we promised to return to the question of easily deformable nuclei where there are large matrix elements from χ_o to low-lying rotational states so that the initial single-particle excitation has a high probability of decaying into an excitation where the initial particle has only slightly less energy. This state, therefore, has a width almost as large as the initial width. In this case, one should separate out the strong transitions to the low-lying collective states which, together with the initial channel, we term the "chosen channels" and treat them separately in a system of coupled equations as has been done by Sano, Yoshida, and Terasawa,[49] (references to extensive earlier work by Yoshida and others are given in this article) and by Chase, Wilets, and Edmonds.[50]

In fact, the preceding development can be generalized so that $V-\bar{V}$ is a matrix between chosen channels, $|o\rangle$ becoming the space of the chosen channels and Λ_o excluding these from occurring in intermediate states, essentially reproducing Yoshida's formalism. This generalization is within the spirit of the optical model where the distortion provided by the central potential is supposed to represent the average effects from the great number of channels and correspondingly large number of degrees of freedom which cannot be conveniently treated in detail.

8. Special Models

It would not be possible to evaluate $\mathcal{W}$ from either Eq. (56) or Eq. (58) since the matrix elements $\langle on|V-\bar{V}|p\rangle$ or $\langle on|V-\bar{V}|jm\rangle$ cannot be calculated owing to the complexity of the $\Phi^{(p)}(\mathbf{r},\xi)$ and the $\chi_j(\xi)$. It would be difficult to evaluate $\mathcal{W}$ even from the equations of the last section since these would involve using wave functions in a complex well of finite extent. Consequently, somewhat idealized models have been introduced to carry out this evaluation and we now discuss their relationship to the development here.

The interior of a large nucleus has been represented as a Fermi gas. In this case, the absorption, Eq. (67), is approximated by

$$W_n=\frac{\pi}{D}\{\langle on|\sum V_{oi}-\sum\bar{V}_{oi}|\bar{q}\rangle^2\}_{\mathrm{Av}}, \quad (69)$$

where the Fermi sea $|o\rangle$ is taken as an antisymmetrized product function of plane waves, $|n\rangle$ is a plane wave of energy above the top of the Fermi sea, and $|\bar{q}\rangle$ is a

state of the same energy as $|on\rangle$ in which a second particle has been lifted above the sea.

In such a model it is immaterial how large the interval I over which the average is taken in calculating $\mathfrak{W}$ or W. No features are left in the model capable of giving rapid variations in the quantities calculated, so that the scattering amplitude is a smoothly varying function of energy and the average phase, for reasonable intervals, is very close to the actual phase. Consequently, one does not need to carry the iI in the energy denominator in the actual evaluations. However, in establishing the validity of Eq. (67), it was necessary to carry the iI in the compound-state picture.

A second model, which is not so useful in obtaining numerical values, but is instructive, has been used by Wigner.[51] He assumes that levels $|jm\rangle$ are evenly spaced in energy and that the matrix elements $\langle jm|\delta V|kl\rangle$, where δV is the perturbation, are all equal in absolute value but of random sign as long as $E_{jm}-E_{kl}$ is less than a certain quantity (in the Wigner formalism the energy eigenvalues are real) and zero for greater energy differences. He then finds, under certain conditions which are probably satisfied in the nuclear case, a Lorentzian form, i.e., the shape Eq. (33), for the strength function in the region of the single-particle resonance. This implies, according to Eq. (33), that W is constant with respect to energy.

A third model, used by Bloch,[36] is similar to Wigner's except that the point at which he makes his assumption of random signs and equality of matrix elements is in the perturbation expansion, Eq. (57). This means that only the even powers of the expansion contribute. His analysis shows that the largest number of nonvanishing terms comes from the lowest-order term, corresponding to Eq. (58). However, such assumptions of random signs are unjustified in the actual physical case, and for the case of a large nucleus, when approximated by a Fermi sea, it is found that the third term in the series,[52] which would be zero under the above assumptions, actually contributes about as much to the imaginary part of the potential as the second term. Furthermore, the second term appears to be much less predominant when the exclusion principle is taken into account since the second-order processes are severely inhibited.

Once one has adopted a simplified model, any mechanism that might be present in the actual nucleus to give rapid variations in the parameters has been dropped, and consequently, the result is insensitive to the interval over which one averages since the actual phase is very nearly the same as the average phase. However, the inclusion of iI when the compound-state energies W_p were present was necessary to establish the relevance of these models to the calculation of the average phase.

It seems reasonable that at high bombarding energies, where the widths of the compound states are much greater than their spacings, the actual scattering amplitude varies smoothly with energy and that fluctuations are small. Consequently, one might expect the actual amplitude to be the same as the average one here, and again, the calculated amplitude would be insensitive to the distances over which one averaged. This would explain why our formulas for the average amplitude have the same form as those of Watson and collaborators for higher energy scattering even though no average over energy is carried out in their work.

However, in the intermediate region where fluctuations may still be important and in the low-energy region, it is necessary to carry out the averages over energy as we have done.

We have not discussed the fluctuation scattering in much detail. This is because it is not possible to evaluate this directly; since the corresponding particles stay in the nucleus a long time, any expansion in terms of successive collisions is bound to fail. In fact, because of their long duration in the nucleus, these particles would seem to correspond to those described by the original extreme compound-nucleus model. Consequently, it is reasonable to neglect phase relations here on the average, and this results in angular distributions symmetrical about 90°. There is always some ambiguity about adding in the fluctuation scattering, but if one can calculate the average scattering amplitude so as to obtain the first term on the right-hand side of Eq. (26), one obtains a lower limit on the cross section for the relevant process. This is especially useful in inelastic scattering where similar considerations apply. An application of this is indicated in the next section. Furthermore, if the above assumptions are justified, the fluctuation scattering is rather structureless and simply tends to make the minima in the shape-elastic scattering less pronounced without altering the general picture.

IV. DIRECT INTERACTION IN THE DIPOLE PHOTOEFFECT AND IN RADIATIVE CAPTURE

We treat one case in which the incident and emerging particles are different, namely, that in which one of the particles is a photon. As discussed in Sec. I, a giant resonance is observed in the absorption of photons by complex nuclei in the region of ~15 Mev for medium weight nuclei. Collective models give a natural explanation of the absorption mechanism but not of the number of fast protons emerging which is orders of magnitude in excess of the predictions of the statistical theory. Direct interactions are necessary to account for them. This does not mean that emission of fast protons is the dominant decay process; this constitutes only ~1% of the total decay processes in heavy nuclei where such decays are strongly inhibited by the Coulomb barrier. However, this is several orders of magnitude above the predictions of 10^{-4} or 10^{-5} for the probability given by the statistical theory. The

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

inverse (p,γ) processes violate the predictions of the statistical theory in just as striking a fashion.[53,54]

Whereas this theory would predict a strong decrease in the cross section with increasing energy or increasing atomic number A, the experimental results of Cohen[55] show no such decreases for proton energies in excess of 5 Mev. This is an added indication that direct processes play an important role.

Wilkinson[14] has proposed a model for the (γ,p) reaction which incorporates the physical features that follow from the detailed theory. He views the absorption of the γ-ray by one of the nucleons as leading first to an excited state of the single particle of width W in the complex well. This is just the single-particle excitation discussed earlier. One then associates with this level the natural width Γ for escape from the nucleus and the width $2W$ for absorption into compound states. Consequently, the proportion $\Gamma/(\Gamma+2W)$ escape, carrying off essentially the full energy of the γ-ray. This reproduces the observed order-of-magnitude of fast protons when averaged over the relevant single-particle levels.

We now extend the formalism to treat the absorption of radiation following Brown and Levinger.[56] This extension is similar to that carried out in the framework of the continuum theory of nuclear reactions by Peaslee.[57] The wave function of the system in which γ-rays are absorbed consists only of outgoing waves and is described by

$$\Psi(\mathbf{r},\xi)=\sum_{\alpha',j} S_{\gamma\alpha',j}\chi_j(\xi)\psi_{\alpha'}{}^{j+}(\mathbf{r}), \quad r>R, \tag{70}$$

where $S_{\gamma\alpha',j}$ is the amplitude for γ-ray absorption with emission of the nucleon into channel α', leaving the residual nucleus in state j. For $r<R$ we have

$$\Psi=\Psi_o(\mathbf{r},\xi)+\textstyle\sum_p a_p\Phi^{(p)}(\mathbf{r},\xi), \tag{71}$$

where the $\Phi^{(p)}$ are the compound-state functions, Eq. (13). Here Ψ_o is the wave function of the initial nucleus (it being understood that a γ-ray is present). It can often be adequately represented as a shell-model wave function. The coordinate of the particle to be emitted is labeled by $\mathbf{r}$ whereas those of all the other A$-$1 particles are labeled by ξ. Thus, although there is a symmetry between the A particles, we choose to describe the absorption by a particular particle for simplicity, and our description consequently singles out this particle. The interaction with the radiation field (electric field $\mathcal{E}$ along the z axis normalized to a flux of one photon per cm^2 sec) is described by H_I where

$$H_I=e\mathcal{E}_z=e(2\pi\hbar\omega)^{\frac{1}{2}}z \tag{72}$$

on restricting the consideration to the dipole interaction. Since the coupling to the radiation field is weak, the a_p's are needed only to first order which can easily be done by requiring Ψ to satisfy the Schrödinger equation to that order. We have

$$H_I\Psi_o=(E-H)\textstyle\sum a_p\Phi^{(p)}=\sum a_p(E-W_p)\Phi^{(p)}. \tag{73}$$

By multiplying on the left by $\Phi^{(p)}$ and integrating, we find

$$a_p=\langle p|H_I|o\rangle/(E-W_p), \tag{73.1}$$

as expected from perturbation theory. Here we use $|o\rangle$ for Ψ_o; E is the full energy of the system. We now measure it from the ground state of the initial nucleus, $E=\hbar\omega$, where $\hbar\omega$ is the γ-ray energy.[58]

We easily obtain $S_{\gamma\alpha',j}$ by equating Ψ from Eqs. (71) and (73) at $r=R$, multiplying by $\chi_j(\xi)\Theta_\alpha(\theta,\varphi)$ and integrating over $d^3\xi$ and $d\Omega$.

$$S_{\gamma\alpha',j}=\frac{1}{\phi_{\alpha'}{}^{j+}(R)}\sum_p\int_0^R d^3\xi\int d\Omega\Phi^{(p)}(\xi,\mathbf{R})\chi_j(\xi)\times\Theta_\alpha(\theta,\varphi)\frac{\langle p|H_I|o\rangle}{W_p-\hbar\omega}. \tag{74}$$

From the expansion, Eq. (14), we find

$$S_{\gamma\alpha',j}=\frac{1}{\phi_{\alpha'}{}^{j+}(R)}\sum_{p,m}\tilde{\phi}_m{}^j(R)\langle jm|p\rangle\frac{\langle p|H_I|o\rangle}{W_p-\hbar\omega}, \tag{74.1}$$

This gives a cross section

$$\sigma_{\gamma\alpha',j}=\frac{\hbar k_j}{Mc}|S_{\gamma\alpha',j}|^2. \tag{75}$$

Once again we are concerned with the average scattering amplitude $\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}$ which can be obtained from Eq. (74.1) by replacing $\hbar\omega$ by $\hbar\omega+iI$ in the denominator, i.e.,

$$\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}=\frac{1}{\phi_{\alpha'}{}^{j+}(R)}\sum_{p,m}\tilde{\phi}_m{}^j(R)\langle jm|p\rangle\frac{\langle p|H_I|o\rangle}{W_p-E-iI}, \tag{76}$$

which in the equivalent Green's function description is

$$\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}=\frac{1}{\phi_{\alpha'}{}^{j+}(R)}\sum_m\tilde{\phi}_m{}^j(R)\left(jm\left|\frac{1}{H-E-iI}H_I\right|o\right). \tag{76.1}$$

The equivalence of Eqs. (76) and (76.1) is easily shown by inserting the unit operator $|p\rangle\langle p|$ to the left of H_I in the latter. By employing an expansion similar to that, Eq. (45) for $(H-\hbar\omega-iI)^{-1}$, one has

[53] F. Beck, Nuclear Phys. 9, 140 (1958/9).
[54] A. M. Lane and J. E. Lynn, Nuclear Phys. 11, 646 (1959).

[57] D. C. Peaslee, Phys. Rev. 88, 812 (1952).

[58] This means that the energy of the excited particle, in terms of single-particle excitations, is measured from the energy of the ground state of the original nucleus, whereas earlier, the E associated with the single particle in our discussion of elastic scattering was its energy at $r=\infty$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$$\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}=\frac{1}{\phi_{\alpha'}{}^{i+}(R)}\sum_m \tilde{\phi}_m{}^{i}(R)\Big\{\frac{\langle jm|H_I|o\rangle}{\bar{E}_{jm}-\hbar\omega-iI}$$
$$-\frac{1}{\bar{E}_{jm}-\hbar\omega-iI}\frac{1}{\bar{E}_{kl}-\hbar\omega-iI}$$
$$\times\Big[\langle jm|V-\tilde{V}|kl\rangle$$
$$-\frac{\langle jm|V-\tilde{V}|p\rangle\langle p|V-\tilde{V}|kl\rangle}{W_p-\hbar\omega-iI}\Big]$$
$$\times\langle kl|H_I|o\rangle\Big\}, \quad (77)$$

where the label k refers to the excited states of the A$-$1 particles as does j. We now limit consideration to the case in which $\epsilon_{jm}\cong E$, i.e., the single particle takes off approximately the full energy of the γ-ray. The other case, in which $\epsilon_{jm}-E\gg W_m$ where W_m is the absorption relating to the single-particle state $|m\rangle$, can be treated just as our simple case of scattering, Sec. III, 4.

Perturbation theory here amounts to expanding the $(W_p-\hbar\omega-iI)^{-1}$ and the first term is obtained by replacing $|p\rangle(W_p-\hbar\omega-iI)^{-1}\langle p|$ by

$$\sum_{i,n}|in\rangle(E_{in}-\hbar\omega-iI)^{-1}\langle in|.$$

As discussed in Sec. III, 6, this is a good approximation because the states $|n\rangle$ are mainly at a lower excitation than the original $|l\rangle$ which are the states reached by the single particle absorbing approximately the full γ-ray energy, and consequently the spread of the $\langle p|in\rangle^2$ is small compared with W_l, the absorption pertaining to the state $|l\rangle$.

We can expect the first term on the right-hand side of Eq. (77) to be a good approximation to $\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}$. We consider first the case $|jm\rangle=|kl\rangle$. In this case, it is useful to consider both terms in square brackets together. If it is remembered that the overlap between $|j\rangle$ and the part of Ψ_o relating to the ξ-particles is large only if the states of the ξ-particles are similar in both (the final factor $\langle kl|H_I|o\rangle$ ensures this will be as shown), and if $\tilde{V}$ is chosen so as to satisfy Eq. (49), then the term in square brackets here very nearly vanishes, any remaining effects coming from the small differences between $|j\rangle$ and the ξ-variable part of Ψ_o. Since the two terms in the square brackets are separately of order W_m, and since the denominators in front never become smaller than W_m+I, then if the two terms cancel to a good approximation, their contribution can be neglected. Estimates of the first term in square brackets for the case $|jm\rangle\neq|kl\rangle$ indicate that it is of order $(\bar{V}/\text{A})/(W_l+I)$ relative to the first term. Corrections for this term may have to be made in some cases. We do not pursue this further but assume that the first term gives a sufficiently good approximation. In any case, we have indicated that the series expansion converges for large enough I so that we could calculate further terms if necessary for good numerical results.

The first term on the right-hand side of Eq. (77) looks very much like the matrix element that would describe the photonuclear process for a particle in a complex well, since the states $|p\rangle$ have disappeared. Remnants of the fact that the process is really not a single-particle one remains however, in that states $|j\rangle$ are employed rather than the shell-model excited states which are just the states in which particles fill all but one of the A levels from the bottom of the well. To show how we can dispose of the details of the states $|j\rangle$, let us assume that the initial state Ψ_o is well represented by the shell-model state so that we can write

$$\Psi_o(\mathbf{r},\xi)=\Omega(\xi)\psi_{m'}(\mathbf{r}), \quad (78)$$

where $\psi_{m'}(\mathbf{r})$ is the bound state occupied initially by the r-particle. Then we can split the matrix element coming into the first term of Eq. (77) into

$$\langle jm|H_I|o\rangle=\langle m|H_I|m'\rangle\int_0^R\Omega(\xi)\chi_j(\xi)d^3\xi$$
$$=\langle m|H_I|m'\rangle Q_{\Omega j}, \quad (78.1)$$

defining $Q_{\Omega j}$. Let us assume that only one single-particle level contributes essentially to a given channel which is often a good approximation. The cross section arising from the first term on the right-hand side of Eq. (77) is

$$\sum_i\frac{\hbar k_j}{Mc}|\langle S_{\gamma\alpha',j}\rangle_{\text{Av}}|^2\cong\sum_i\Gamma_{\alpha'j}Q_{\Omega j}{}^2\frac{1}{\hbar c}\left|\frac{\langle m|H_I|m'\rangle}{\bar{E}_{jm}-\hbar\omega-iI}\right|^2, \quad (79)$$

where

$$\Gamma_{\alpha'j}\equiv\frac{\hbar k_j}{M}\left|\frac{1}{\phi_{\alpha'}{}^{i+}(R)}\right|^2|\tilde{\phi}_m{}^{i}(R)|^2, \quad (79.1)$$

is the full single-particle escape width taken at energy $\hbar\omega-\epsilon_j$ where ϵ_j is the excitation energy of the state j. From completeness, the probability of finding the state Ω somewhere in the excited states $|j\rangle$ is unity, i.e.,

$$\sum_j Q_{\Omega j}{}^2=1. \quad (79.2)$$

From the development in Sec. III, 7, the width of the distribution of ϵ_j about $|\epsilon_{m'}|$ is $W_{m'}$, where $W_{m'}$ can be interpreted as the width of the hole in state m'. Consequently, we see that the width of the total distribution of emitted fast particles is the sum of the width for the excited particle and of the width of the hole in the shell-model states.

These arguments do not add any new physical features to Wilkinson's model but show how this simple description relates to the many-body description.

Similar equations can be used to estimate the cross section for direct radiative capture of neutrons or

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

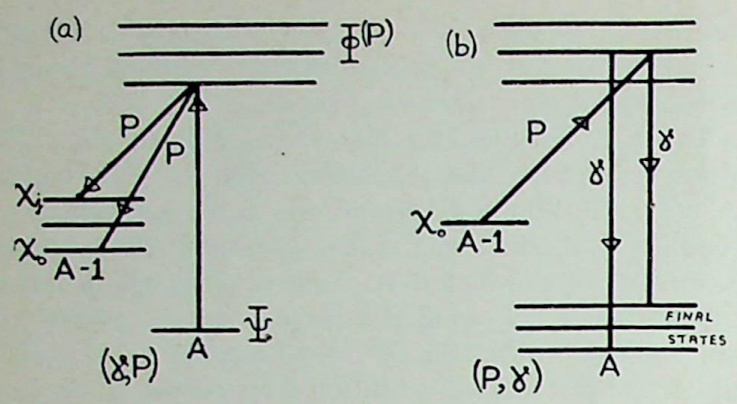

FIG. 12. Relation of the (γ,p) to (p,γ) reactions.

protons. An extensive description of this is contained in work by Lane and Lynn.[54]

The cross sections for (γ,p) and (p,γ) reactions can of course easily be related. We have the (γ,p) cross section by summing over all members of the configuration of the final $A-1$ nucleons (see Fig. 12). The (γ,p) reaction goes from the ground state to all final states j. The (p,γ) reaction may go from the ground state $\chi_o(\xi)$ to the various final states [see Fig. 12(b)] which contain an appreciable component of $\chi_o(\xi)$. (The wave function for the ξ-particles must remain the same since H_I is a function only of $\mathbf{r}$.) Further, the final state must contain an appreciable component of $\psi_{m'}(\mathbf{r})$, the relevant single-particle state in the well. From arguments similar to those already used the probability of finding $\chi_o\psi_{m'}$ somewhere in the ground or low-excited states is essentially unity. Thus, the cross section for the (p,γ) reaction, summed over the ground and low-excited states, is given by Eq. (79) with two minor changes: (i) we multiply by the usual factor k_γ^2/k_p^2 from detailed balance or dispersion theory where k_γ and k_p are γ-ray and proton wave numbers; (ii) we use $\Gamma_{\alpha' j}$ without the averaging implied in the sum over j in Eq. (79) since the incident particle now has a unique energy.

V. DISCUSSION OF OTHER FORMALISMS

Recently, a unified theory of nuclear reactions has been formulated by Feshbach,[59] and many of the relations between compound-nucleus parameters and those of the optical model have been derived by him, although he does not develop the perturbation theory described in Sec. III. Conceptually, his formalism has the advantage that it avoids the introduction of a joining radius. However, his formalism does not seem to be as convenient for making many of the arguments of Sec. III and Sec. IV as the one used here. In any case, there is a close connection between his formalism and the one employed here even though they appear quite different at first sight. We briefly demonstrate some of the relationship, trying to preserve most of Feshbach's notation so that one can easily compare our formulas with his papers.

[59] H. Feshbach, Ann. Phys. 5, 357 (1958).

Feshbach employs functions $\Phi_n(\mathbf{r},\xi)$ which are eigenfunctions of the operator $\mathcal{H}$, Eq. (51), and which are, consequently, just the Ω_p of Eq. (51). The Λ_o in Eq. (51) effectively projects off the incident channel so that the Φ_n form a complete set of states in the space orthogonal to that of the incident channel. Hence, one can write the solution of the Schrödinger equation as

$$\Psi(\mathbf{r},\xi)=\chi_o(\xi)u_o(\mathbf{r})+\sum a^{(n)}\Phi_n(\mathbf{r},\xi), \tag{80}$$

and this equation holds for all values of r since the boundary conditions on the Φ_n are taken to be outgoing waves at infinity in case the particle can escape by a channel other than the incident one. In this case, the Φ's form a continuum, and the sum in Eq. (80) is to be understood in a generalized sense to include both a sum over discrete states and an integral over the continuum states. Since the boundary conditions are imposed at infinity, introduction of a channel radius is not necessary.

The $a^{(n)}$ are determined by requiring Ψ to satisfy the Schrödinger equation $H\Psi=E\Psi$, and one finds

$$a^{(n)}=\frac{\int\Phi_n(\mathbf{r},\xi)V(\mathbf{r},\xi)\chi_0(\xi)u_0(\mathbf{r})d^3\xi d^3r}{E-\mathcal{E}_n}, \tag{81}$$

where we have used Feshbach's notation in denoting the eigenvalues of Φ_n by $\mathcal{E}_n$. Our $a^{(n)}$ are the same as his Λ_n. One also finds, by multiplying the Schrödinger equation on the left by $\chi_o(\xi)$ and integrating over $d^3\xi$, that

$$(T-\bar{V}-E)u_0(\mathbf{r})+\sum a^{(n)}\int\chi_o(\xi)V(\mathbf{r},\xi)\Phi_n d^3\xi=0. \tag{82}$$

By substituting the $a^{(n)}$ from Eq. (81), one finds that $u_o(\mathbf{r})$ obeys the equation

$$(T+\mathcal{U}-E)u_o(\mathbf{r})=0, \tag{83}$$

where $\mathcal{U}$ is Feshbach's generalized optical potential

$$\mathcal{U}=\bar{V}(r)+\sum_n\frac{\int\chi_0(\xi)V(\mathbf{r},\xi)\Phi_n(\mathbf{r},\xi)d^3\xi\int\Phi_n(\mathbf{r}',\xi)V(\mathbf{r}',\xi)\chi_0(\xi)d^3\xi}{E-\mathcal{E}_n}, \tag{83.1}$$

and $\mathcal{U}$ is an integral (nonlocal) operator. One can easily make further connections between our formalism and his by noting that his matrix H_{ij} is just

$$H_{ij}=\int\chi_i(\xi)H\chi_j(\xi)d^3\xi.$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In the very low energy region in which only elastic scattering is possible, the main difference between the two formalisms results from the fact that the incident channel occurs in our $\Phi^{(p)}$ but not in Feshbach's Φ_n. The width corresponding to this channel is contained in our complex W_p, whereas one must essentially invert a matrix—which can be done in a straightforward fashion—to introduce the widths into the denominators of the scattering amplitude in the formalism of Feshbach. The discussion following Eq. (51) shows that the eigenfunctions $\Phi^{(p)}$ and Φ_n are, aside from the above difference, very nearly the same.

The difference between the formalisms is that one can start from a formalism without joining radius, as Feshbach does, in which case the expression for the wave function is simple, but the transition to the scattering amplitude is somewhat complicated in detail. On the other hand, one can begin with a joining radius, in which case the scattering amplitude is simply obtained, and then carry out various sums as we have done to obtain results in which this radius does not appear. Whereas the former procedure has conceptual advantages, the intermediate formulas seem simpler in the latter procedure and the arguments about the spectrum of the compound states, which we have made to establish perturbation theory, appear to be simpler.

A more general formalism for nuclear reactions has been given by Bloch,[36] and we have referred to his work at several points. By appropriate choice of representation, one can obtain either the Wigner-Eisenbud or Kapur-Peierls theory from his formalism. Making the arguments of this article in his formalism would be completely equivalent to the treatment here, and we have chosen the simpler notation of the less general treatment.

Finally, many of the arguments of this article were first formulated in the Wigner-Eisenbud formalism. This is especially true of the development of Sec. III, 3 as shown by a given reference. However, for uniformity we have chosen to restate most of these arguments in our formalism which is just as suitable for them and is probably simpler for other considerations as discussed in Sec. I.

ACKNOWLEDGMENTS

The author would like to acknowledge his debt to Professor R. E. Peierls for countless helpful suggestions and criticisms relevant to the development presented here. He is also greatly indebted to Dr. C. T. De Dominicis. Many other colleagues at Birmingham have been helpful, and Dr. A. M. Lane has contributed numerous helpful suggestions.

I. INTRODUCTION

CONSIDERABLE information about the bremsstrahlung process has accumulated during the past several years. This information includes various cross-section calculations and measurements, which have helped to provide a more accurate description of the process. Unfortunately this material has never been assembled and integrated in an easily referenced form, although some general reviews[1] on the subject are available. This paper provides a coherent summary of the bremsstrahlung cross-section formulas and related data. The theoretical formulas and their specific limitations are presented in a form convenient for practical calculations. Estimates of their accuracy are given for cases where comparisons can be made with experimental results. Correction factors are indicated in either numerical or analytical form. A brief summary of other data pertaining to electron-electron and to thick target bremsstrahlung is also included. No results are presented for electron and photon polarization effects.

Section IIB briefly discusses the problem of making exact cross-section calculations and indicates the general types of calculations that have been completed. A summary of the various cross-section formulas is given in Sec. IIC. Section IID gives useful graphical information derived from the various formulas in IIC. Section IIE lists corrections that can be applied to the above

formulas. In Sec. IIF, experimental bremsstrahlung cross sections are compared with the theoretical results contained in Secs. IIC and D. Conclusions with regard to the accuracy of the theory are presented in Sec. IIG. Section III summarizes the very sparse material available on electron-electron bremsstrahlung. Finally, Sec. IV gives a brief treatment of thick target bremsstrahlung with information on the bremsstrahlung angular distributions (IVA), the spectra (IVB), and the production efficiencies (IVC).

II. BREMSSTRAHLUNG CROSS SECTIONS

The cross sections discussed in this section apply to the bremsstrahlung process[2] in which an electron is decelerated in the field of an atomic nucleus. These cross sections give direct estimates of the properties of the radiation emitted when electrons are incident on *thin*[3] targets, and provide basic data for analyzing the *thick* target bremsstrahlung considered in Sec. IV.

A. Symbols, Constants, and Energy-Momentum Relations

E_0, E = initial and final total energy of the electron in a collision, in m_0c^2 units.†

$\mathbf{p}_0, \mathbf{p}$ = initial and final momentum of the electron in a collision, in m_0c units.

T_0, T = initial and final kinetic energy of the electron in a collision, in m_0c^2 units.†

$k, \mathbf{k}$ = energy and momentum of the emitted photon, in m_0c^2 and m_0c units.†

$\mathcal{E}_0$ = total energy of an electron incident on a thick target, in m_0c^2 units.†

$\mathcal{T}_0$ = kinetic energy of an electron incident on a thick target, in m_0c^2 units.†

θ_0, θ = angles of $\mathbf{p}_0$ and $\mathbf{p}$ with respect to $\mathbf{k}$.

ϕ = angle between the planes $(\mathbf{p}_0,\mathbf{k})$ and $(\mathbf{p},\mathbf{k})$.

$d\Omega_k$ = element of solid angle, $\sin\theta_0 d\theta_0 d\phi$, in the direction of $\mathbf{k}$.

$d\Omega_p$ = element of solid angle, $\sin\theta d\theta d\phi$, in the direction of $\mathbf{p}$.

$\mathbf{q}$ = momentum transferred to the nucleus, in m_0c units.
$= \mathbf{p}_0 - \mathbf{p} - \mathbf{k}$; $q^2 = p_0^2 + p^2 + k^2 - 2p_0k\cos\theta_0 + 2pk\cos\theta - 2p_0p(\cos\theta\cos\theta_0 + \sin\theta\sin\theta_0\cos\phi)$.

β_0, β = ratio of the initial and final electron velocity in a collision to the velocity of light.

Z = atomic number of target material.

$d\sigma_j$ = bremsstrahlung cross section, differential with respect to the parameter j, in units of cm² per atom per incident electron.

$d\tau$ = volume element.

$\mathbf{r}$ = radius vector from a center, in units of the Compton wavelength, $\lambda\!\!\!^{-}_0$.

α = angle of $\mathbf{k}$ with respect to the direction of the electron beam incident on a thick target.

N_0 = 6.03×10^{23} atoms (or molecules) per mole.

c = 3.00×10^{10} cm per sec.

e = 4.80×10^{-10} esu = 1.60×10^{-19} coulomb.

e^2 = 1.44×10^{-13} Mev cm.

h = $h/2\pi = 6.58\times10^{-22}$ Mev sec = 1.05×10^{-27} erg sec.

hc = 12.4 kev-angstroms.

$\hbar c$ = 1.97×10^{-11} Mev cm.

hc/e^2 = 137.

m_0 = 9.11×10^{-28} g (electron mass).

m_0c^2 = 0.511 Mev.

$\lambda\!\!\!^{-}_0$ = $\hbar/m_0c = 3.86\times10^{-11}$ cm (Compton wavelength).

r_0 = $e^2/m_0c^2 = \lambda\!\!\!^{-}_0/137 = 2.82\times10^{-13}$ cm (classical electron radius).

$\bar{\phi}$ = $Z^2r_0^2/137 = Z^2\ 5.78\times10^{-28}$ cm².

a_0 = $\hbar^2/m_0e^2 = 0.530\times10^{-8}$ cm (radius of hydrogen atom).
$= 137\lambda\!\!\!^{-}_0 = (137)^2 r_0$

ϕ_0 = $8\pi r_0^2/3$ (Thomson formula) = 6.64×10^{-25} cm².

e^2/a_0 = $2I_0 = 27.2$ ev.

I_0 = ionization energy of hydrogen atom = $1/2(137)^2$ in m_0c^2 units.

Z^2I_0 = ionization energy of K electron ($if \ll 1$).

1 Mev = 1.60×10^{-6} erg.

$E_0^2 = p_0^2 + 1$, $E^2 = p^2 + 1$.

$E_0 = T_0 + 1$, $E = T + 1$.

$$E_0 = \frac{1}{(1-\beta_0^2)^{\frac{1}{2}}}, \quad E = \frac{1}{(1-\beta^2)^{\frac{1}{2}}}$$

$E_0 = k + E$.

$p_0 = [T_0(T_0+2)]^{\frac{1}{2}}$, $p = [T(T+2)]^{\frac{1}{2}}$

$$p_0 = \frac{\beta_0}{(1-\beta_0^2)^{\frac{1}{2}}}, \quad p = \frac{\beta}{(1-\beta^2)^{\frac{1}{2}}}.$$

$$\beta_0 = \frac{p_0}{E_0}, \quad \beta = \frac{p}{E}.$$

B. Types of Cross-Section Calculations

The bremsstrahlung cross section $d\sigma$, for single photon emission in a large cubic box of side L, is given by the transition probability per atom per electron divided by the incoming electron velocity. This cross section

[2] Except for electron-electron bremsstrahlung which is briefly considered in Sec. III, no results are presented for other bremsstrahlung processes, involving for example the acceleration of positrons or protons.

[3] A target is defined to be thin if both the electron scattering and energy loss processes have a negligible influence on the energy and angular distributions of the bremsstrahlung. Order of magnitude estimates of such thin targets for particular energy regions can be found in the references listed in Sec. IIG.

† This system of units for the symbols is used consistently throughout this paper. For cases in which the data are given in Mev units, these symbols have the multiplicative factor 0.51; for example, the kinetic energy in Mev units is represented by the quantity $0.51T_0$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

can be expressed in dimensions of cm² as

$$d\sigma=\frac{w}{(p_0c/E_0)}\left(\frac{\hbar}{m_0c}\right)^3 L^3, \qquad \text{(II-1)}$$

where

$$w=(2\pi/\hbar)\rho_f|H_{if}|^2. \qquad \text{(II-2)}$$

The term ρ_f is the density of final states and can be written as

$$\rho_f=\frac{pEk^2dkd\Omega_kd\Omega_pL^6}{(2\pi)^6m_0c^2}. \qquad \text{(II-3)}$$

The term H_{if} is the matrix element for the transition of the system from an initial state before the emission of the photon to a final state after the emission. The quantity $|H_{if}|^2$ in formula (II-2) can be written as

$$|H_{if}|^2=\left(\frac{2\pi}{k}\frac{e^2}{\hbar c}\right)(m_0c^2)^2 \times\left|\int\psi_f^*(\lambda^*\cdot\alpha)e^{-i\mathbf{k}\cdot\mathbf{r}}\psi_i d\tau\right|^2 L^{-9}. \qquad \text{(II-4)}$$

In the foregoing, λ is the unit polarization vector of the photon, α is the Dirac matrix, and ψ_i and ψ_f are the Dirac wave functions for the initial and final electrons, respectively. Therefore the cross section in cm² can be written as

$$d\sigma=\frac{137r_0^2}{(2\pi)^4}\frac{pE_0E}{p_0}\left|\int\psi_f^*(\lambda^*\cdot\alpha)e^{-i\mathbf{k}\cdot\mathbf{r}}\psi_i d\tau\right|^2 \times kdkd\Omega_kd\Omega_p. \qquad \text{(II-5)}$$

The important quantity to be evaluated is the matrix element H_{if}, defined in formula (II-4).

The problem of evaluating an "exact" expression for the cross section involves, therefore, the use in the matrix element of "exact" wave functions, which describe an electron in a screened, nuclear Coulomb field. It is not possible to solve the Dirac wave equation in closed form for an electron in a Coulomb field, primarily because the wave function must be represented as an infinite series.[4] Therefore, various approximate wave functions and procedures have been used.

The cross-section calculations that have been made may be classified either as nonrelativistic or relativistic depending on whether the Schrödinger or Dirac form of the Hamiltonian is used for the electron and field system. The calculations have been carried out with (a) nonrelativistic Coulomb wave functions (Sommerfeld); (b) relativistic Coulomb wave functions (Sommerfeld-Maue) valid to first order in $(Z/137)^2/l$, where l is the angular momentum quantum number that is the summation index in the expansion of the wave function; and (c) free-particle wave functions perturbed to first order in Z (Born-approximation procedure).

The nonrelativistic cross-section formulas derived in the dipole approximation by Sommerfeld[5] with Coulomb wave functions have a complicated form with hypergeometric functions and are difficult to evaluate. Some numerical estimates[6] of the Sommerfeld cross sections have been made for selected values of the electron energy, the target atomic number, and the photon energy. However, the theory is only valid when β_0 is small compared to unity, and can be expected to break down for initial electron energies greater than a few kilovolts. In addition, the theory disregards screening effects, which are important for very low energies and for targets with high atomic numbers. Because of these limitations, results of the Sommerfeld theory are not presented here.

Cross-section calculations with relativistic Coulomb wave functions (Sommerfeld-Maue) including screening corrections have been made by Olsen, Maximon, and Wergeland[7] and by Olsen and Maximon.[8] Their formulas are valid only in the extreme-relativistic region (above 50 Mev). Their results have the form of an additive correction factor to the Born-approximation formulas.

The cross-section formulas calculated by the Born-approximation procedure with free-particle wave functions are available in a relatively simple analytical form for nonrelativistic and relativistic energies, with or without screening. In general, the Born approximation theory becomes less reliable as (a) the atomic number of the target increases, (b) the initial electron energy decreases, and (c) the photon energy approaches the high-frequency limit. In spite of their limited validity, the Born-approximation formulas have been surprisingly successful in predicting the properties of the bremsstrahlung radiation. Even where there is a breakdown of the Born approximation, the accuracy of the cross-section formulas is still reasonably good, and in the worst cases (except at the high-frequency limit), they can be expected to give at least the correct order of magnitude. Therefore, this paper emphasizes the Born-approximation cross-section formulas and includes various theoretical and empirical corrections to these formulas. Detailed references to the many papers in which these formulas are derived are given in Table III.

C. Bremsstrahlung Cross-Section Formulas and Classification Diagrams

A general classification of the various differential forms of the bremsstrahlung cross section is presented in Chart 1 for the Born-approximation formulas and in Chart 2 for the extreme-relativistic formulas that con-

[4] A detailed discussion of this problem is given by H. A. Bethe and L. C. Maximon, Phys. Rev. 93, 768 (1954).

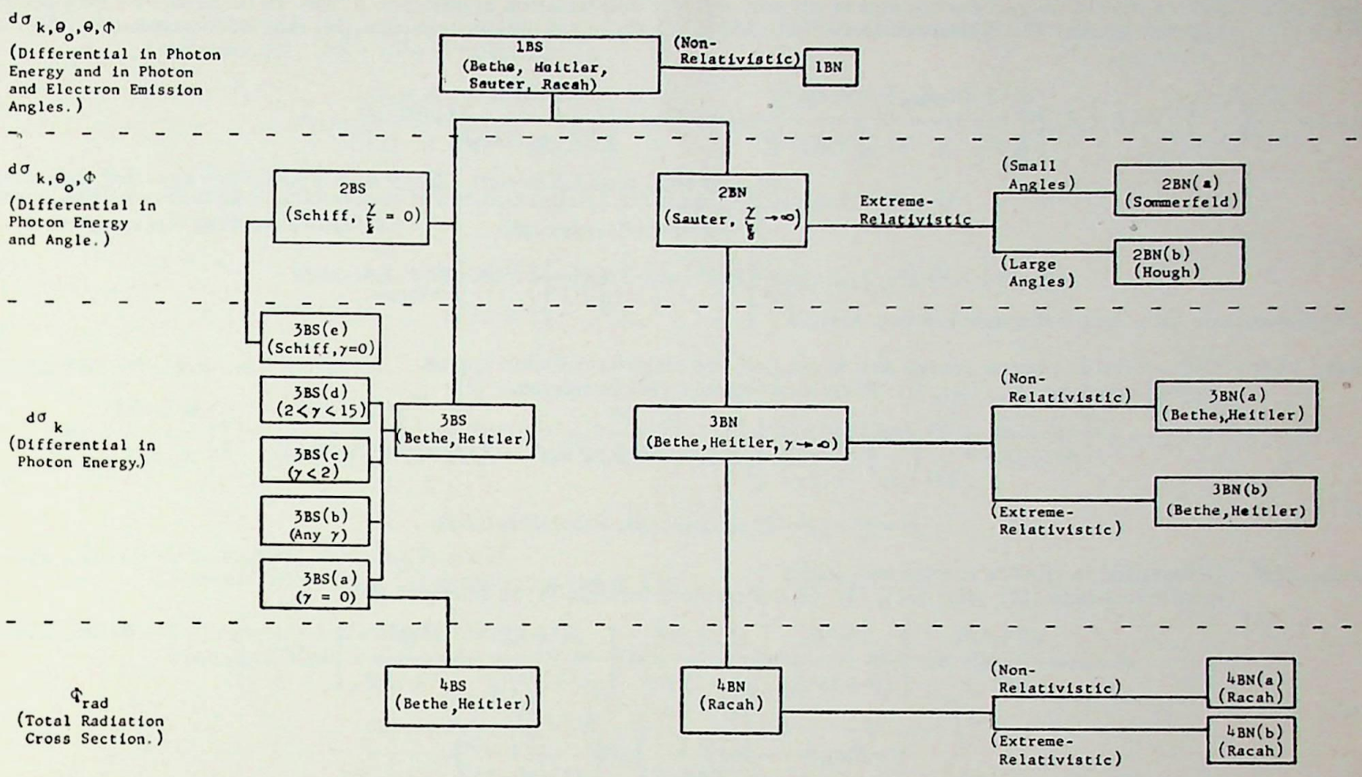
CHART 1

Born Approximation Cross Section Formulas



tain the Coulomb correction. The formulas represented are summed over the directions of the electron spin and the photon polarization vectors, and thus do not include all of the possible differential forms of the cross section. The primary formula gives the cross section that is differential in photon energy and in photon and electron emission angles. The remaining formulas that branch out from this starting point are divided into two main groups that are designated as screened or non-screened. Further subdivisions are made; these depend on the type of screening approximation, and on whether nonrelativistic, extreme-relativistic, small-angle, or large-angle approximations are used. For most of the cases, the charts include the names of the principal authors associated with a particular formula.

The formulas are identified as follows: (a) the number applies to a particular differential form of the cross section; (b) the first letter indicates either B for Born approximation (Chart 1) or C for Coulomb correction (Chart 2); (c) the second letter indicates either S for screening or N for no screening; and (d) the last letter a, b, or c indicates further subdivisions for specific approximations. The following notation has been adopted here. The differential forms of the bremsstrahlung cross section are designated by the symbol, $d\sigma_{\alpha,\beta,\ldots}$. This symbol is the bremsstrahlung cross section that is differential only with respect to the parameters given by the subscripts $\alpha, \beta, \cdots$, and is explicitly defined by $d\sigma_{\alpha,\beta\ldots} \equiv (d^n\sigma/d\alpha d\beta\cdots)d\alpha d\beta\cdots$. The unit of the cross section, $d\sigma_{\alpha,\beta\ldots}$, is cm^2 per atom per incident electron.

The symbols and definitions for the specific cross sections are as follows.

(a) $d\sigma_{k,\theta_0,\theta,\phi}$ is the bremsstrahlung cross section that is differential with respect to the photon energy, k, and to the photon and electron emission angles, θ_0, θ, and ϕ. This formula contains the parameters E_0, Z, k, θ_0, θ, and ϕ.

TABLE I. Born-approximation cross-section formulas.

Formula 1BS—Differential in photon energy and in photon and electron emission angles.
Approximation (H). Reference formulas: (13) in reference (a), (2) in reference (b), (13) in reference (c), (29) in reference (e).

$$d\sigma_{k,\theta_0,\theta,\phi}=\frac{Z^2}{137}\left(\frac{r_0}{2\pi}\right)^2[1-F(q,Z)]^2\frac{dk}{k}\frac{p}{p_0}\frac{d\Omega_k d\Omega_p}{q^4}\left\{\frac{p^2\sin^2\theta}{(E-p\cos\theta)^2}(4E_0^2-q^2)+\frac{p_0^2\sin^2\theta_0}{(E_0-p_0\cos\theta_0)^2}(4E^2-q^2)\right.$$
$$\left.-\frac{2pp_0\sin\theta\sin\theta_0\cos\phi\,(4EE_0-q^2)}{(E-p\cos\theta)(E_0-p_0\cos\theta_0)}+\frac{2k^2(p^2\sin^2\theta+p_0^2\sin^2\theta_0-2pp_0\sin\theta\sin\theta_0\cos\phi)}{(E-p\cos\theta)(E_0-p_0\cos\theta_0)}\right\},$$

where

$$q^2=p^2+p_0^2+k^2-2p_0k\cos\theta_0+2pk\cos\theta-2p_0p(\cos\theta\cos\theta_0+\sin\theta\sin\theta_0\cos\phi)$$

and $F(q,z)$ = atomic form factor discussed in Sec. IIE(3).

Formula 1BN—Differential in photon energy and in photon and electron emission angles.
Approximations (H), (B), (I). Reference formula (17) in reference (c).

$$d\sigma_{k,\theta_0,\theta,\phi}=\frac{Z^2}{137}\left(\frac{r_0}{\pi}\right)^2\frac{dk}{k}\frac{p}{p_0}\frac{d\Omega_k d\Omega_p}{q^4}\{p^2\sin^2\theta+p_0^2\sin^2\theta_0-2pp_0\sin\theta\sin\theta_0\cos\phi\},$$

where

$$q^2=p^2+p_0^2-2pp_0(\cos\theta\cos\theta_0+\sin\theta\sin\theta_0\cos\phi).$$

Formula 2BS—Differential in photon energy and angle.
Approximations (H), (G), (M), (J), (K). Reference formula (1) in reference (h).

$$d\sigma_{k,\theta_0}=\frac{4Z^2r_0^2}{137}\frac{dk}{k}y\,dy\left\{\frac{16y^2E}{(y^2+1)^4E_0}-\frac{(E_0+E)^2}{(y^2+1)^2E_0^2}+\left[\frac{E_0^2+E^2}{(y^2+1)^2E_0^2}-\frac{4y^2E}{(y^2+1)^4E_0}\right]\ln M(y)\right\},$$

where

$$y=E_0\theta_0,\quad\frac{1}{M(y)}=\left(\frac{k}{2E_0E}\right)^2+\left(\frac{Z^{\frac{1}{3}}}{111(y^2+1)}\right)^2.$$

Comment: This formula becomes Formula 2BN(a) when $Z=0$ in $M(y)$.

Formula 2BN—Differential in photon energy and angle.
Approximations (H), (B). Reference formulas: (11) in reference (d), (4.1) in reference (f).

$$d\sigma_{k,\theta_0,\phi}=\frac{Z^2r_0^2}{8\pi137}\frac{dk}{k}\frac{p}{p_0}d\Omega_k\left\{\frac{8\sin^2\theta_0(2E_0^2+1)}{p_0^2\Delta_0^4}-\frac{2(5E_0^2+2EE_0+3)}{p_0^2\Delta_0^2}-\frac{2(p_0^2-k^2)}{Q^2\Delta_0^2}+\frac{4E}{p_0^2\Delta_0}\right.$$
$$+\frac{L}{pp_0}\left[\frac{4E_0\sin^2\theta_0(3k-p_0^2E)}{p_0^2\Delta_0^4}+\frac{4E_0^2(E_0^2+E^2)}{p_0^2\Delta_0^2}+\frac{2-2(7E_0^2-3EE_0+E^2)}{p_0^2\Delta_0^2}+\frac{2k(E_0^2+EE_0-1)}{p_0^2\Delta_0}\right]$$
$$\left.-\left(\frac{4\epsilon}{p\Delta_0}\right)+\left(\frac{\epsilon^Q}{pQ}\right)\left[\frac{4}{\Delta_0^2}-\frac{6k}{\Delta_0}-\frac{2k(p_0^2-k^2)}{Q^2\Delta_0}\right]\right\},$$

where

$$L=\ln\left[\frac{EE_0-1+pp_0}{EE_0-1-pp_0}\right];\quad\Delta_0=E_0-p_0\cos\theta_0;\quad\epsilon=\ln\left[\frac{E+p}{E-p}\right];\quad\epsilon^Q=\ln\left[\frac{Q+p}{Q-p}\right]$$
$$Q^2=p_0^2+k^2-2p_0k\cos\theta_0.$$

Formula 2BN(a)—Differential in photon energy and angle.
Approximations (H), (B), (J), (K).

$$d\sigma_{k,\theta_0,\phi}=\frac{2Z^2r_0^2}{\pi137}\frac{E}{E_0}\frac{dk}{k}d\Omega_k\left\{\frac{16(\theta_0E_0)^2E_0^2}{(1+\theta_0^2E_0^2)^4}-\frac{(E_0+E)^2E_0}{E(1+\theta_0^2E_0^2)^2}+2\ln\left(\frac{EE_0}{k}\right)\left[\frac{(E^2+E_0^2)E_0}{E(1+\theta_0^2E_0^2)^2}-\frac{4\theta_0^2E_0^4}{(1+\theta_0^2E_0^2)^4}\right]\right\}.$$

Comment: This formula was obtained from formula 2BN by making the high-energy and small-angle approximations. The same result is obtainable from formula 2BS by setting $Z=0$ in $M(y)$.

Formula 2BN(b)—Differential in photon energy and angle.
Approximations (H), (B), (J), (L). Reference formula (8) in reference (i).

$$d\sigma_{k,\theta_0,\phi}=\frac{Z^2r_0^2}{4\pi137}\frac{E}{E_0^3}\frac{dk}{k}\frac{d\Omega_k}{(1-\cos\theta_0)^2}\left\{\left(\frac{E_0^2+E^2}{EE_0}\right)\sin^2\theta_0\ln\frac{2E_0E}{k}-\frac{(5E_0+2E)}{E_0}+\frac{2[E^2-2E_0^2\ln(k/E_0)]}{E_0E}[1-\cos\theta_0]\right.$$
$$\left.-\frac{E[Q^2+E(k-E_0\cos\theta_0)]}{E_0Q^2(1-\cos\theta_0)}-\frac{E_0k(1-\cos\theta_0)}{EQ^3}[3Q^2+E(E_0+k)]\ln\left(\frac{Q+E}{Q-E}\right)\right\}.$$

where $Q^2=E^2+2kE_0(1-\cos\theta_0)$.

TABLE I.—(*Continued*).

Formula 3BS—Differential in photon energy.
Approximations (H), (J). Reference formulas: (31), (34), (35) in reference (a); (62) in reference (b); (21), (26) in reference (c); (56)–(58b) in reference (j).

$$d\sigma_k=\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left\{\left(1+\left(\frac{E}{E_0}\right)^2\right)\left[\frac{\phi_1(\gamma)}{4}-\tfrac{1}{3}\ln Z\right]-\frac{2}{3}\frac{E}{E_0}\left[\frac{\phi_2(\gamma)}{4}-\tfrac{1}{3}\ln Z\right]\right\}.$$

Formula 3BS(a)—Complete screening ($\gamma=0$ or $\phi_1(\gamma=0)=4\ln 183$; $\phi_2(\gamma=0)=\phi_1(\gamma=0)-\frac{2}{3}$).
Formula 3BS with $\gamma=0$.

$$d\sigma_k=\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left\{\left[1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right]\ln(183Z^{-\frac{1}{3}})+\frac{1}{9}\frac{E}{E_0}\right\}.$$

Formula 3BS(b)—Arbitrary screening.

$$d\sigma_k=\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left\{\left(1+\left(\frac{E}{E_0}\right)^2\right)\left[\int_\delta^1(q-\delta)^2(1-F(q))^2\frac{dq}{q^3}+1\right]-\frac{2}{3}\frac{E}{E_0}\left[\int_\delta^1\left(q^3-6\delta^2q\ln\frac{q}{\delta}+3\delta^2q-4\delta^3\right)(1-F(q))^2\frac{dq}{q^4}+\frac{5}{6}\right]\right\},$$

where

$$\delta=k/(2E_0E).$$

Formula 3BS(c)—Intermediate screening I ($\gamma<2$).
Formula 3BS with $\phi_1(\gamma)$ and $\phi_2(\gamma)$ given in Fig. 1.

Formula 3BS(d)—Intermediate screening II ($2<\gamma<15$).
Formula 3BS with $\phi_1(\gamma)=\phi_2(\gamma)=19.19-4\ln\gamma-4c(\gamma)$ with $c(\gamma)$ given in Fig. 2.

$$d\sigma_k=\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left[1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right]\left[\ln\frac{2E_0E}{k}-\tfrac{1}{2}-c(\gamma)\right].$$

Formula 3BS(e)—Differential in photon energy.
Approximations (H), (G), (M), (J). Reference formula (3) in reference (h).

$$d\sigma_k=\frac{2Z^2r_0^2}{137}\frac{dk}{k}\left\{\left(1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right)\left(\ln M(0)+1-\frac{2}{b}\tan^{-1}b\right)+\frac{E}{E_0}\left[\frac{2}{b^2}\ln(1+b^2)+\frac{4(2-b^2)}{3b^2}\tan^{-1}b-\frac{8}{3b^2}+\frac{2}{9}\right]\right\},$$

where

$$b=\left(\frac{2E_0EZ^{\frac{1}{3}}}{111k}\right);\quad\frac{1}{M(0)}=\left(\frac{k}{2E_0E}\right)^2+\left(\frac{Z^{\frac{1}{3}}}{111}\right)^2.$$

Comment: This formula is obtained from formula 50 of reference (b).

Formula 3BN—Differential in photon energy.
Approximations (H), (B). Reference formulas: (15) in reference (a), (16) in reference (c), (17) in reference (d), (37) in reference (e).

$$d\sigma_k=\frac{Z^2r_0^2}{137}\frac{dk}{k}\frac{p}{p_0}\left\{\tfrac{4}{3}-2E_0E\left(\frac{p^2+p_0^2}{p^2p_0^2}\right)+\frac{\epsilon_0E}{p_0^3}+\frac{\epsilon E_0}{p^3}-\frac{\epsilon\epsilon_0}{p_0p}+L\left[\frac{8E_0E}{3p_0p}+\frac{k^2(E_0^2E^2+p_0^2p^2)}{p_0^3p^3}+\frac{k}{2p_0p}\left(\left(\frac{E_0E+p_0^2}{p_0^3}\right)\epsilon_0-\left(\frac{E_0E+p^2}{p^3}\right)\epsilon+\frac{2kE_0E}{p^2p_0^2}\right)\right]\right\},$$

where

$$L=2\ln\left[\frac{E_0E+p_0p-1}{k}\right];\quad\epsilon_0=\ln\left(\frac{E_0+p_0}{E_0-p_0}\right);\quad\epsilon=\ln\left(\frac{E+p}{E-p}\right).$$

Formula 3BN(a)—Differential in photon energy.
Approximations (H), (B), (I). Reference formula (18) in reference (c).

$$d\sigma_k=\frac{Z^2r_0^2}{137}\frac{16}{3}\frac{dk}{k}\frac{1}{p_0^2}\ln\left(\frac{p_0+p}{p_0-p}\right).$$

Formula 3BN(b)—Differential in photon energy.
Approximations (H), (B), (J). Reference formulas: (16) in reference (a), (21) in reference (c), (56) in reference (j).

$$d\sigma_k=\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left[1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right]\left[\ln\left(\frac{2E_0E}{k}\right)-\tfrac{1}{2}\right].$$

Comment: This formula results directly from Formula 3BS(e) when $b\to 0$ and from formula 3BS when $\gamma\to\infty$.

$$\phi_{\text{rad}}=\frac{4Z^2r_0^2}{137}\left[\ln(183Z^{-\frac{1}{3}})+\frac{1}{18}\right].$$

Formula 4BN—Total radiation cross section.
Approximations (H), (C). Reference formulas: (29) in reference (c), (41) in reference (e).

$$\phi_{\text{rad}}=\frac{Z^2r_0^2}{137}\left\{\frac{(12E_0^2+4)}{3E_0p_0}\ln(E_0+p_0)-\frac{(8E_0+6p_0)}{3E_0p_0^2}[\ln(E_0+p_0)]^2-\tfrac{4}{3}+\frac{2}{E_0p_0}[F(x)]\right\},$$

where

$$F(x)=\int_0^x\frac{\ln(1+y)}{y}dy \quad \text{and} \quad x=2p_0(E_0+p_0).$$

For small x, F can be expanded in the power series:

$$F(x)=x-\frac{x^2}{4}+\frac{x^3}{9}-\frac{x^4}{16}+\cdots.$$

For large x, F is given by

$$F(x)=\tfrac{1}{6}\pi^2+\tfrac{1}{2}(\ln x)^2-F(1/x).$$

Formula 4BN(a)—Total radiation cross section.
Approximations (H), (C), (I). Reference formulas: (32) in reference (c), (21) in reference (d).

$$\phi_{\text{rad}}=(16/3)(Z^2r_0^2/137).$$

Formula 4BN(b)—Total radiation cross section.
Approximations (H), (C), (J). Reference formulas: (33) in reference (c), (41′) in reference (e), (61) in reference (j), (46) in (a), (22) in (d).

$$\phi_{\text{rad}}=\frac{4Z^2r_0^2}{137}(\ln 2E_0-\tfrac{1}{3}).$$

(b) $d\sigma_{k,\theta_0,\phi}$ is the bremsstrahlung cross section that is differential with respect to the photon energy, k, and the emission angles θ_0 and ϕ. It can be obtained by integrating the differential cross section in (a) over the direction of the outgoing electron. This formula contains the parameters E_0, Z, k, and θ_0.

(c) $d\sigma_k$ is the bremsstrahlung cross section that is differential with respect to the photon energy k. It can be obtained by integrating the differential cross section in (a) over the emission directions of the photon and the electron. This formula contains the parameters E_0, Z, and k.

(d) ϕ_{rad} is the only cross-section symbol used here that does not represent a differential form of the bremsstrahlung cross section. It is equal to the quantity, $(1/E_0)\int_0^{T_0}kd\sigma_k$. This form of a total bremsstrahlung cross section integrated over photon energy and photon and electron emission angles was introduced by Heitler,[9] who has defined it as the cross section for the energy lost by radiation. This formula contains the parameters E_0 and Z.

The Born-approximation formulas that apply to Chart 1 are presented in Table I, and the extreme-relativistic formulas with the Coulomb correction that apply to Chart 2 are presented in Table II. The important references and approximations for the formulas in Tables I and II are listed in Table III. The explicit expressions for the formulas in Tables I and II are not necessarily the same as the formulas in the original references because the attempt is made to use consistent units and symbols, with energies and momenta expressed in m_0c^2 and m_0c units, respectively.

(1) *Born-Approximation Cross-Section Formulas*

The Born-approximation calculations require the initial and final electron kinetic energies in a collision to be large enough to satisfy the conditions: $(2\pi Z/137\beta_0)$, $(2\pi Z/137\beta)\ll 1$. At extreme-relativistic energies, the cross sections predicted by the Born-approximation formulas are larger than the true cross sections. For example, the value of the total cross section predicted for lead by the Born-approximation formula is about 10% larger than the value predicted by more accurate formulas.[7] At very low energies, the situation is reversed and the Born-approximation cross section is smaller than the true cross section. The energy region in which the Born-approximation formulas require only small corrections is approximately between 4 and 10 Mev for the initial electron kinetic energy. As a rough guide, it is estimated that Born-approximation formulas for the total radiation cross section, ϕ_{rad}, are correct to within 10% for initial electron kinetic energies above 2 Mev and within a factor of two below 2 Mev.

(2) *Extreme-Relativistic Cross-Section Formulas with the Coulomb Correction*

The formulas in Table II are valid for arbitrary Z and have been developed in a series of papers by Bethe and Maximon,[10] Olsen,[11] Olsen, Maximon and Wergeland,[7] Olsen and Maximon,[8,12] and Davies, Bethe, and Maximon.[13] Their calculations were carried out (a) with Sommerfeld-Maue wave functions, and (b) with the extreme relativistic approximations: E_0, E, $k \gg 1$, and $p_0\theta_0 \sim 1$. These formulas are estimated[10] to have an accuracy of the order of $(Z/137)^2(\ln E/E)$ which is better than 2% for electron kinetic energies above 50 Mev and for Z equal to 80.

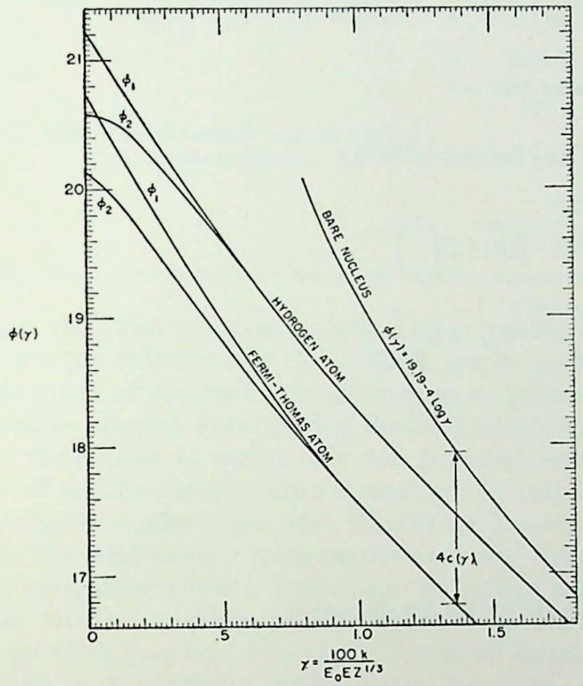

FIG. 1. Screening factors,[28] $\phi_1(\gamma)$ and $\phi_2(\gamma)$, for electron-nuclear bremsstrahlung plotted as a function of $\gamma = 100k/E_0EZ^{\frac{1}{3}}$. The curve marked "Hydrogen atom" was calculated[41] with exact wave functions. The curves for the Thomas-Fermi atom and a bare nucleus differ by the quantity $4c(\gamma)$, where the function $c(\gamma)$ is plotted in Fig. 2.

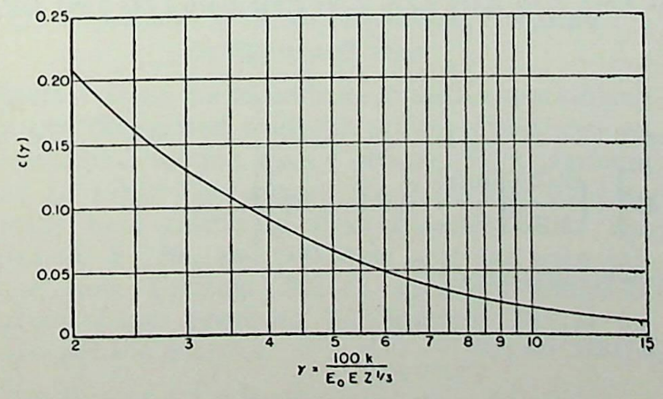

FIG. 2. Screening factor,[28] $c(\gamma)$, for electron-nuclear bremsstrahlung plotted as a function of $\gamma = 100k/E_0EZ^{\frac{1}{3}}$.

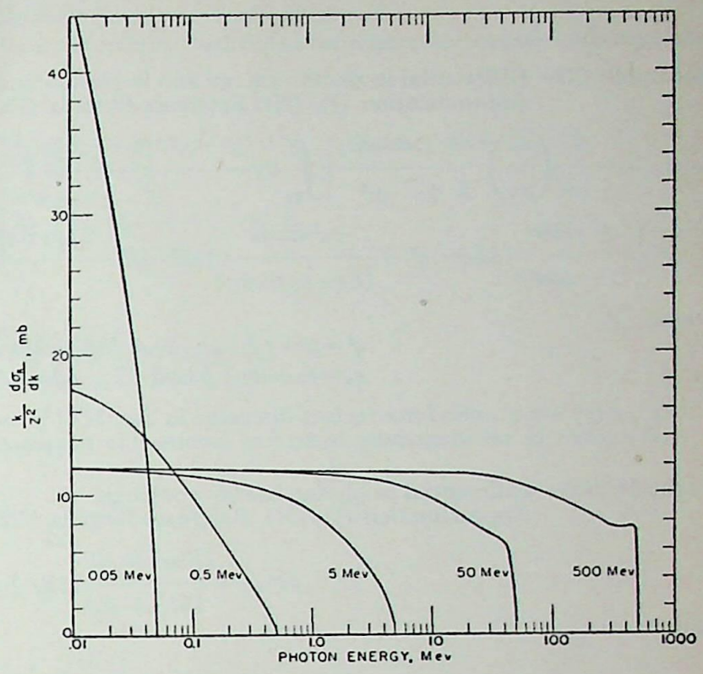

FIG. 3. Dependence of the Born-approximation cross section integrated over the photon directions on the photon and electron energy. The ordinate values for these curves are obtained from Formula 3BN for 0.05- and 0.50-Mev electrons, and from Formula 3BS (e) for 5-, 50-, and 500-Mev electrons.

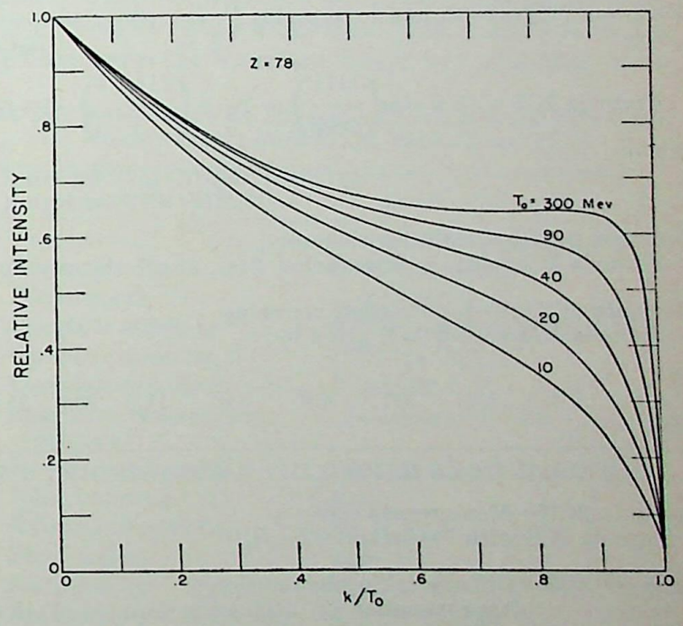

FIG. 4. Dependence of the bremsstrahlung spectrum shape on the electron kinetic energy for a platinum target ($Z=78$). The relative intensity (defined as proportional to the product of the photon energy and number per unit time) is integrated over the photon direction and is normalized to unity for zero photon energies. The intensity values were computed from Formula 3BS(e).

energies, the photon emission angle, and screening corrections is presented in Figs. 3–10. These graphs provide various types of theoretical intercomparisons primarily for energies above 1 Mev. Such a detailed examination of the predictions is useful only for the high-energy region where the theories are reasonably accurate and require much smaller corrections than in the low-energy region. The high-energy intercomparisons rely heavily on the extreme-relativistic predictions of Schiff[14] which depend on the validity of the complete screening approximation [see Sec. IIE (3)]. The Schiff formulas are given in a relatively simple analytical form, and have been used extensively for estimating the spectrum shape from a high-energy accelerator even though other more complicated formulas with intermediate-screening approximations are believed to be more accurate (see Table V).

(1) *Dependence of the Bremsstrahlung Spectrum on Electron Energy*

Figure 3 shows the dependence of the bremsstrahlung spectrum (integrated over the photon directions) on various initial electron kinetic energies for a platinum target ($Z=78$). The spectra for 0.05- and 0.5-Mev electrons were calculated from Formula 3BN. The spectra for 5-, 50-, and 500-Mev electrons were calculated from Formula 3BS(e). Figure 4 compares spectrum shapes predicted by Formula 3BS(e) for various electron energies.

(2) *Dependence of the Bremsstrahlung Spectrum on Photon Angle*

Figures 5(a)–(e) show the dependence of the spectrum shape on the reduced photon angle, $E_0\theta_0$, as obtained from Formula 2BS. The figures show that as the emission angle increases, the relative number of high-frequency photons increases until the trend reverses at the larger angles. For comparison, the spectrum shape integrated over the emission angle is evaluated from

Formula 3BS(e) and is shown by the dashed line. In Figs. 6(a)–(e), the dependence of the cross section (Formula 2BS) on the photon emission angle, θ_0, is plotted for various photon and electron energies.

The spectrum shape integrated[15] over the photon directions with the limits from zero to a maximum value of θ_0 equal to Θ is of practical interest to experimentalists. Figures 7(a)–(e) show the spectra obtained for different values of $E_0\Theta$ by integrating Formula 2BS within the above limits of θ_0. These curves facilitate estimates of the change in thin-target spectra for different experimental arrangements that subtend various angles. In Figs. 8(a)–(c), the curves give estimates of the fraction of the total number of photons at any

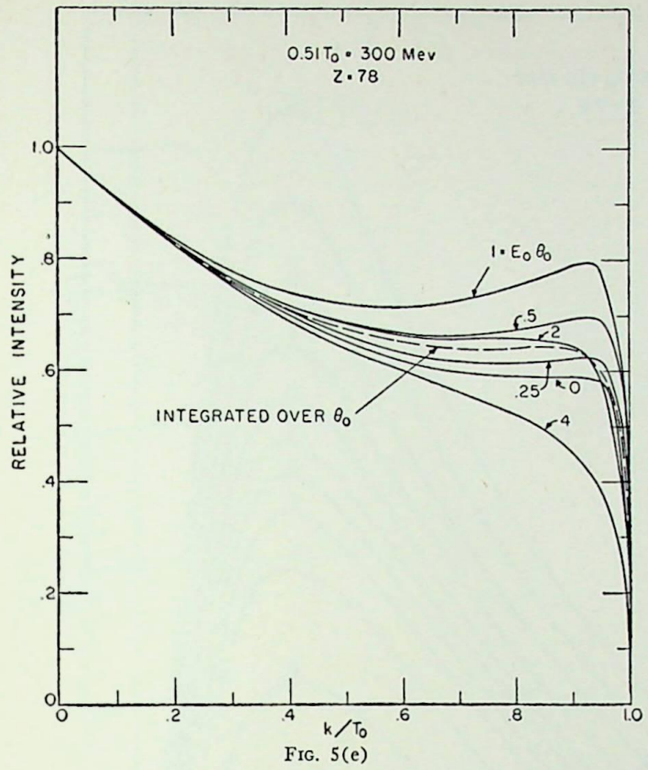

FIG. 5(e)

FIG. 5(a) Dependence of the Schiff spectrum shape on the photon emission angle, θ_0, for 10-Mev electrons and for $Z=78$. The data are obtained from Formula 2BS (solid lines) and from Formula 3BS(e) (dashed line). The values for the intensities (defined as proportional to the product of the photon energy and number per unit time) are normalized to unity at the zero photon energy. (b) Dependence of the Schiff spectrum shape on the photon emission angle, θ_0, for 20-Mev electrons and for $Z=78$. (c) Dependence of the Schiff spectrum shape on the photon emission angle, θ_0, for 40-Mev electrons and for $Z=78$. (d) Dependence of the Schiff spectrum shape on the photon emission angle, θ_0, for 90-Mev electrons and for $Z=78$. (e) Dependence of the Schiff spectrum shape on the photon emission angle, θ_0, for 300-Mev electrons.

given energy that are included within the angular limits from zero to $E_0\Theta$; these curves are obtained by graphical integration from Figs. 6(a), (c), and (e) for initial electron kinetic energies of 10, 40, and 300 Mev.

Figures 5–8 present some predictions of the Born-approximation formulas given in Table I. For comparison, the spectrum shapes as a function of the photon emission angle that are predicted by the more accurate extreme-relativistic Formula 2CS(c) in Table II, are shown in Figs. 9(a) through (e) with a normalization of unity for zero photon energy. The spectra for electron kinetic energies of 10, 20, and 40 Mev, Figs. 9(a), (b), and (c), are predicted with a zero Coulomb correction factor, $f(Z)=0$, in Formula 2CS(c), and the spectra for electron kinetic energies of 90 and 300 Mev, Figs. 9(d) and (e), include the Coulomb correction factor for $Z=78$. A comparison of the spectral shapes with and without the Coulomb correction factor shows only small differences compared to the larger effects that occur with different types of screening approximations.

(3) *Screening Effects and Coulomb Corrections*

Figures 10(a)–(e) intercompare Formula 2BS (0° Schiff), Formula 3BS(c) (Schiff's formula integrated over the photon angle), Formula 3BS (Bethe-Heitler's formula integrated over the photon angle), and the latter formula including the Davies, Bethe, Maximon correction [Formula 3CS and Sec. IIE(1)]. The three curves that are integrated over photon angle are appreciably different in shape. For example, the curves labeled "Schiff" and "Davies, Bethe, Maximon" are 10% different for an electron kinetic energy of 10 Mev at a fractional photon energy of 0.7 with the normalization used in this figure. For the sake of completeness, the spectra corrected for multiple scattering are also plotted in these figures. The multiple scattering correction as calculated by Hisdal[16] is discussed in Sec. IV.

E. Corrections for the Cross-Section Formulas

Various corrections have been obtained for the formulas given in Sec. IIC. These corrections may be classified according to three types: (1) Coulomb corrections, (2) high-frequency-limit corrections, and (3) screening corrections. In each case, the correction is restricted to a particular energy region, and is intended to apply only to the formula for a particular differential form of cross section as specified below.

(1) *Coulomb Corrections*

(*a*) *Nonrelativistic energies.*—In the nonrelativistic region where $T_0 \ll 1$, Elwert[17] has estimated a multiplicative Coulomb correction factor for the cross-section Formula 3BN(a). The Elwert factor, f_E, can be written as

$$f_E=\frac{\beta_0\{1-\exp[-(2\pi Z/137\beta_0)]\}}{\beta\{1-\exp[-(2\pi Z/137\beta)]\}}. \qquad \text{(II-6)}$$

This factor is valid only if $(Z/137)(\beta^{-1}-\beta_0^{-1})\ll 1$. This requirement forbids the use of the Elwert factor near the high-frequency limit. In addition, the Elwert correction was derived on the basis of a comparison between the nonrelativistic Born-approximation and the nonrelativistic Sommerfeld calculations. Therefore the factor is restricted to nonrelativistic electron energies. For higher electron energies (of the order of the electron rest energy), the experimental results in Sec. IIF show that the Elwert factor breaks down. As a rough guide, the Elwert factor may be expected to give results that are accurate to about 10% for electron energies below about 0.1 Mev.

(*b*) *Intermediate energies.*—In the energy region from roughly 0.1 to 2.0 Mev, Coulomb corrections to the Born-approximation formulas are not available in analytical form. Therefore these corrections must be estimated empirically from experimental results (Sec. IIF). For the cross-section formulas differential in photon energy, $d\sigma_k$, such empirical corrections cannot

[16] E. Hisdal, Phys. Rev. **105**, 1821 (1957).
[17] G. Elwert, Ann. Physik **34**, 178 (1939).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

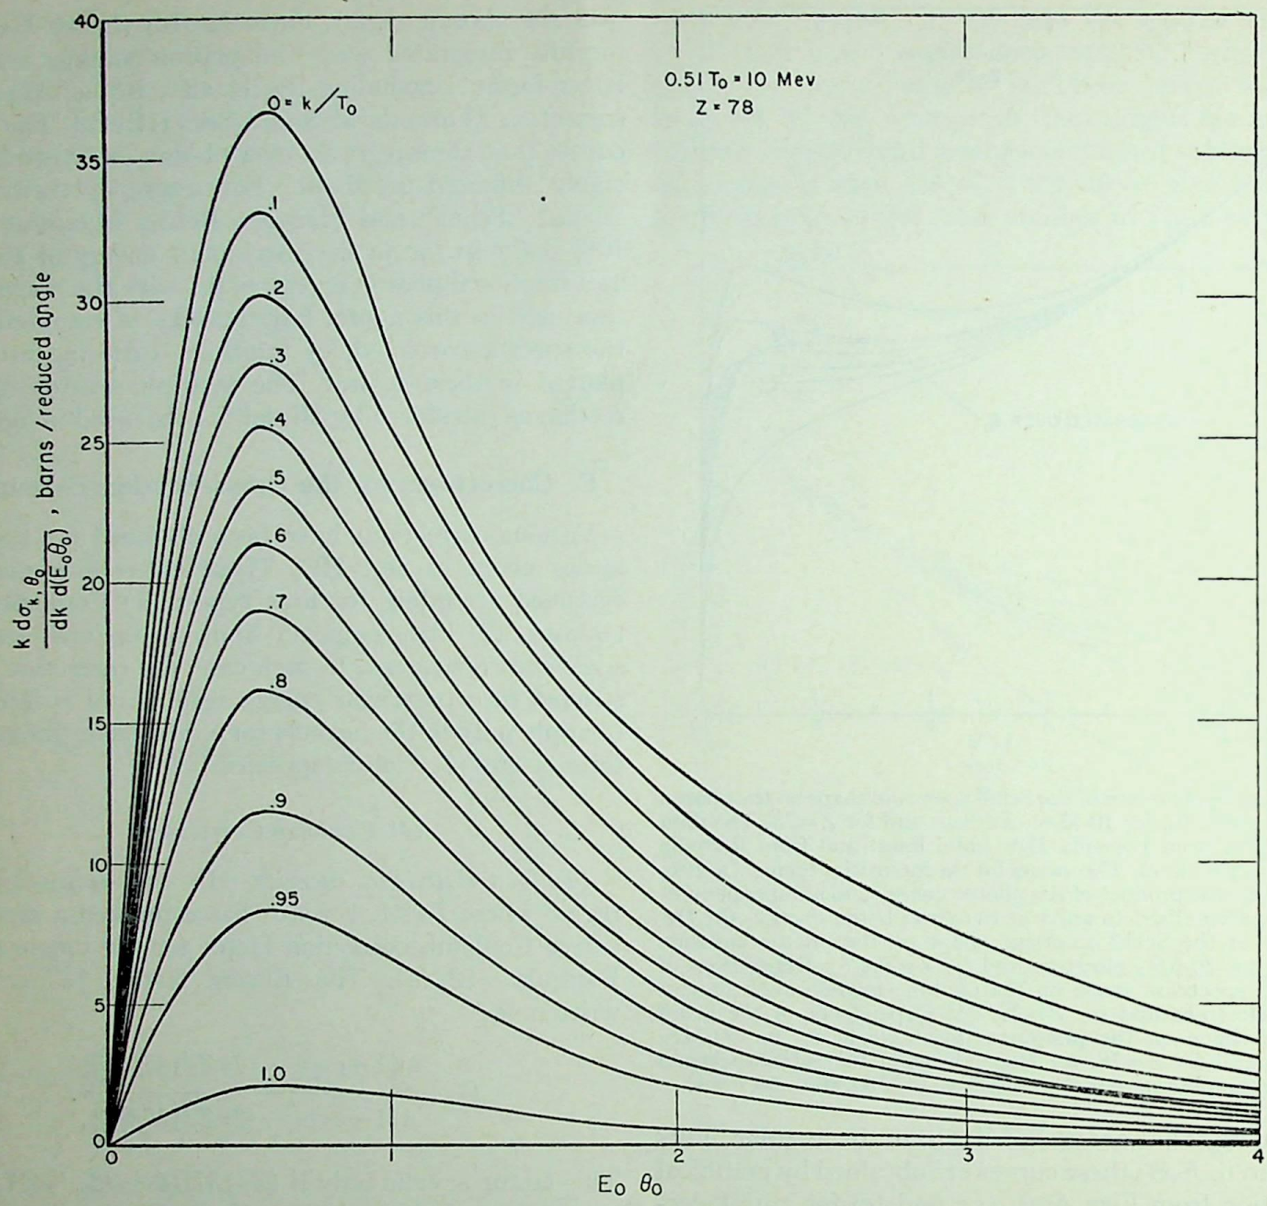

FIG. 6. Angular dependence of the Schiff cross section (Formula 2BS, $Z=78$) at various photon energies for the following electron energies: (a) 10 Mev, (b) 20 Mev, (c) 40 Mev, (d) 90 Mev, and (e) 300 Mev.

(*Figs. 6(b) to 6(e) continued on following pages*)

be determined in enough detail from the available data to cover the whole energy region. However, corrected estimates of the integrated cross section, ϕ_{rad}, are given in Sec. IIF from which empirical correction factors can be obtained. The results indicate that the corrections to the Born-approximation formulas for ϕ_{rad} are as large as a factor of two in the energy region close to the electron rest energy, and less than 10% in the energy region from about 4 to 20 Mev.

(*c*) *Extreme-relativistic energies.*—In this energy region, formulas that include the Coulomb correction for the differential cross sections $d\sigma_{k,\theta_0,\phi}$ and $d\sigma_k$ are given in Table II. A comparison of the formulas in Tables I and II shows that the Coulomb correction can be applied to the Born-approximation formulas for $d\sigma_k$ by the addition of

$$\Delta=-\frac{4Z^2r_0^2}{137}\frac{dk}{k}\left[1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right]f(Z), \quad \text{(II-7)}$$

where $f(Z)$ is approximately equal[13] to $1.20(Z/137)^2$ for low Z and $0.925(Z/137)^2$ for high Z. This additive term is independent of the type of screening approximation that is used and is similar to the correction derived for the pair production process.[11] For lead and energies above 50 Mev, the correction decreases the Born-approximation ϕ_{rad} with intermediate screening by about 10%. The corrected cross section should be accurate to about 2%.

Accurate experimental data corroborating the cross-section values predicted by these formulas are not yet

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

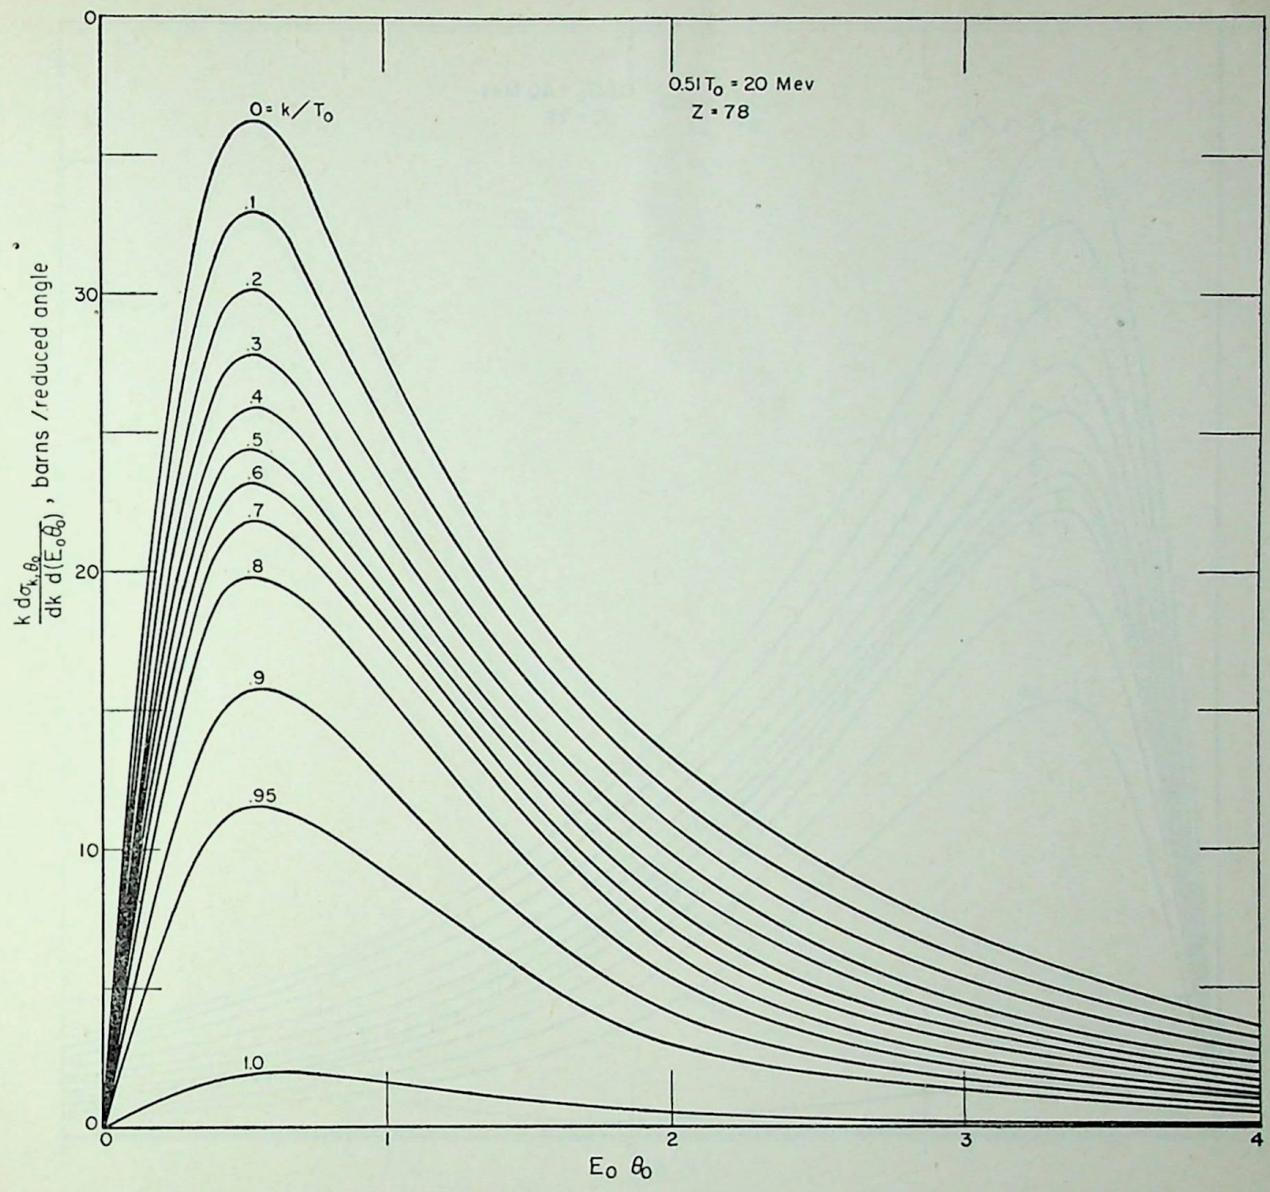

FIG. 6(b)

available. However, confirmation is available in the results of absolute pair cross sections. The ratios of the experimental pair-production cross sections to the Born-approximation cross sections are found to agree with the Davies, Bethe, Maximon[13] values, as shown in Fig. 11.

(2) *High-Frequency-Limit Corrections*

The formulas in Tables I and II are derived on the basis of certain approximations which do not permit an evaluation of the cross section at the high-frequency limit. This shortcoming has been emphasized by various experimental studies[18] which indicate that the cross section has a finite value at this limit.

Recent calculations made in the Sauter approximation (expansion in powers of $Z/137\beta_0$ and $Z/137$) by Fano[19] predict a finite value for the cross section at the high-frequency limit. In contrast, the cross section with the Born-approximation (expansion in powers of $Z/137\beta_0$ and $Z/137\beta$) becomes zero at the limit. The cross-section formulas for the high-frequency limit obtained by Fano are[20]

$$[d\sigma_{k,\theta_0}]_{k=T_0}=\frac{Z^3r_0^2}{137^2}\frac{\beta_0}{k^2E_0^3}\frac{dk}{k}\frac{4\pi\sin^3\theta_0 d\theta_0}{(1-\beta_0\cos\theta_0)^4}$$
$$\times\{1+\tfrac{1}{2}E_0(E_0-1)(E_0-2)(1-\beta_0\cos\theta_0)\} \quad \text{(II-8)}$$

and, after integration over θ_0,

$$[d\sigma_k]_{k=T_0}=4\pi\frac{Z^3}{137^2}r_0^2\frac{dk}{k}\frac{E_0\beta_0}{(E_0-1)^2}$$
$$\times\left\{\frac{4}{3}+\frac{E_0(E_0-2)}{(E_0+1)}\left[1-\frac{1}{2\beta_0E_0^2}\ln\left(\frac{1+\beta_0}{1-\beta_0}\right)\right]\right\}. \quad \text{(II-9)}$$

[18] W. C. Miller and B. Waldman, Phys. Rev. **75**, 425 (1949); Fuller, Hayward, and Koch, *ibid.* **109**, 630 (1958); D. Jamnik (private communication).

[19] U. Fano, Phys. Rev. (to be published).

[20] The cross section differential in θ_0 is proportional to $\sin^3\theta_0$, therefore, both the Sauter-approximation and the Born-approximation calculations predict that the cross section at the high-frequency limit is zero for θ_0 equal to zero.

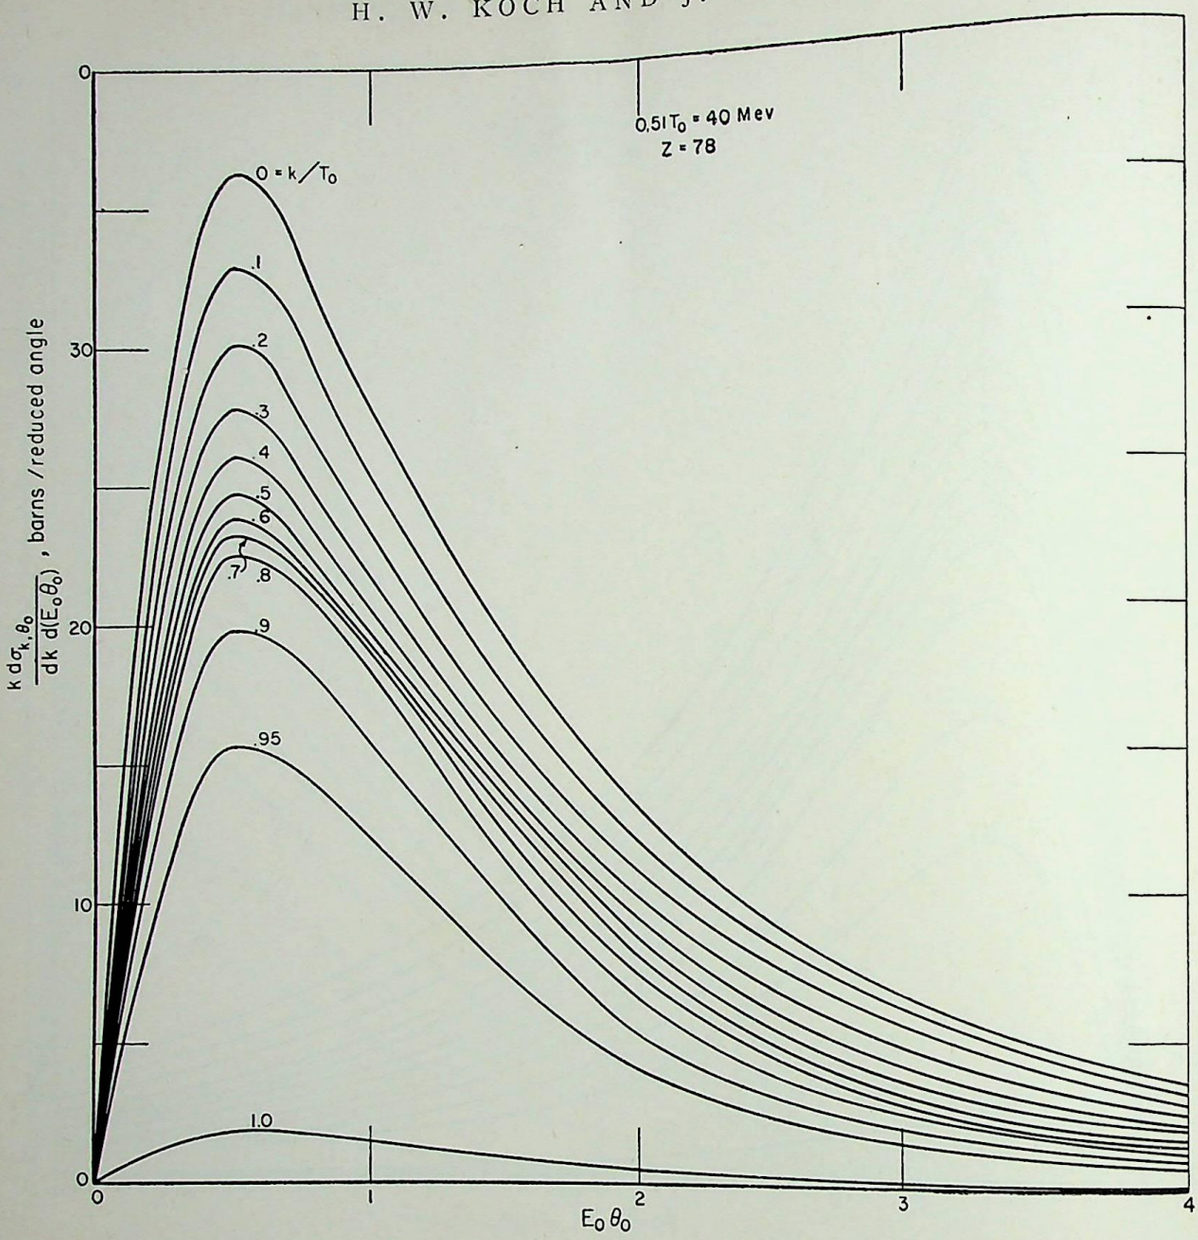

FIG. 6(c)

Fano, Koch, and Motz[21] have shown that Formula (II-9) overestimates the cross section at the high-frequency limit and that a more accurate estimate is obtained for a given electron kinetic energy if this formula is multiplied by the ratio of the "exact" to the Sauter photoelectric cross sections.[22] A summary of their results is given in Fig. 12 which shows the dependence of the bremsstrahlung cross section (integrated over photon direction) at the high-frequency limit on the incident electron energy for aluminum and gold targets. The solid lines (Sauter-Fano) are predicted by Formula (II-9) and the dashed lines (corrected Sauter-Fano) are estimated to be the corrected cross-section values. A comparison of the theoretical and experimental values indicates that the true cross sections at the high-frequency limit are predicted by the dashed curves with an accuracy of approximately 20%.

(3) *Screening Corrections*

Screening effects are most important for extreme-relativistic and for nonrelativistic electron kinetic energies. Corrections for screening have been adequately included only in the extreme relativistic calculations, where $E_0, E, k \gg 1$. The screening corrections for both the Born-approximation and Coulomb-corrected formulas in Tables I and II have been given by the Born-approximation procedure. In these screening calculations, the cross section is proportional to the square of the matrix element

$$M = \int V(r) \exp(i\mathbf{q}\cdot\mathbf{r}) d\tau, \qquad \text{(II-10)}$$

[21] Fano, Koch, and Motz, Phys. Rev. 112, 1679 (1958).

[22] Detailed formulas for the Sauter photoelectric cross section and for the "exact" cross sections of Sauter-Stobbe and Nagasaka are given by Heitler[9] and by G. White Grodstein, Natl. Bur. Standards Circ. No. 583 (1957). The "exact" photoelectric cross-section formula for high energies has been calculated recently by R. H. Pratt, thesis, University of Chicago (June, 1959), and Phys. Rev. (to be published).

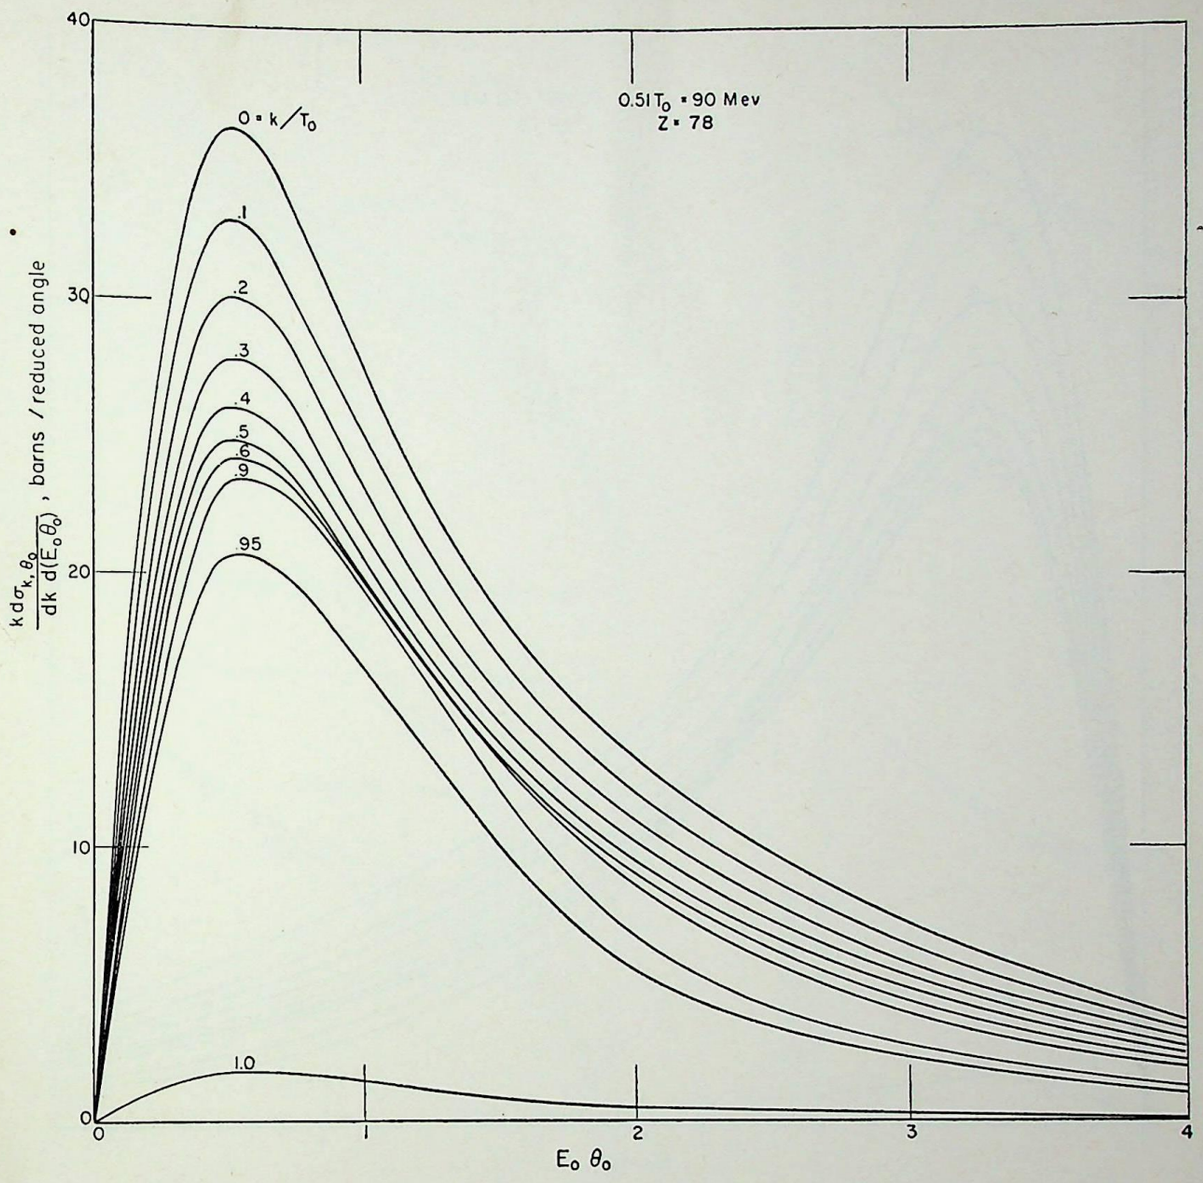

FIG. 6(d)

where $V(r)$ is the potential that determines the interaction for the bremsstrahlung process and **r** is the radius vector in units of the Compton wavelength, $\lambda\!\!\!^{-}_0$. This potential for an atom is represented by the sum, V_n+V_e, where V_n is the potential arising from the nuclear charge and V_e is the potential arising from the charge of the atomic electrons. If the atomic electron form factor is defined as

$$F_e(q,Z)=\frac{4\pi}{Ze}\int\rho(r)\left(\frac{\sin qr}{qr}\right)r^2dr, \qquad \text{(II-11)}$$

where $\rho(r)$ is the electron charge distribution, then the matrix element, M, can be written as proportional to the quantity $(Z/q^2)(F_n-F_e)$. F_n is the nuclear form factor which is roughly equal to unity.[23] Therefore, the unscreened differential cross-section formulas may be corrected for screening effects by including the multiplicative factor $[1-F_e]^2$.

[23] S. J. Biel and E. H. S. Burhop, Proc. Phys. Soc. (London) A68, 165 (1955).

For a Thomas-Fermi model, F_e depends on the quantity $qZ^{-\frac{1}{3}}$ where q has a minimum value of (p_0-p-k). At higher energies, $q_{\min}$ becomes equal to $(k/2E_0E)$ and screening calculations are expressed in terms of $\gamma=100k(E_0EZ^{\frac{1}{3}})^{-1}$. γ is approximately equal to the radius of the Thomas-Fermi atom ($r_{TF}=137Z^{-\frac{1}{3}}$) divided by $r_{\max}$, where $r_{\max}$ is the maximum impact parameter discussed by Heitler[9] and is equal to $q_{\min}^{-1}$. If $r_{\max}$ is large compared to the nuclear radius but small compared to the atomic radius r_{TF}, then γ is large and $F_e(q,Z)=0$. If $r_{\max}$ is of the order of r_{TF}, then $\gamma\sim1$ and screening must be taken into account. If the impact parameter is of the order of the nuclear radius, then the distribution of the nuclear charge must be included by a nuclear form factor[23] although the influence of the distribution of the atomic electrons can be neglected.

The dependence of $r_{\max}$ on the initial electron kinetic energy at all energies can be obtained by setting $r_{\max}$ equal to $(p_0-p-k)^{-1}$. The results are shown in Fig. 13 for k equal to $0.1T_0$, $0.5T_0$, and $0.9\,T_0$. Also, the dashed

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

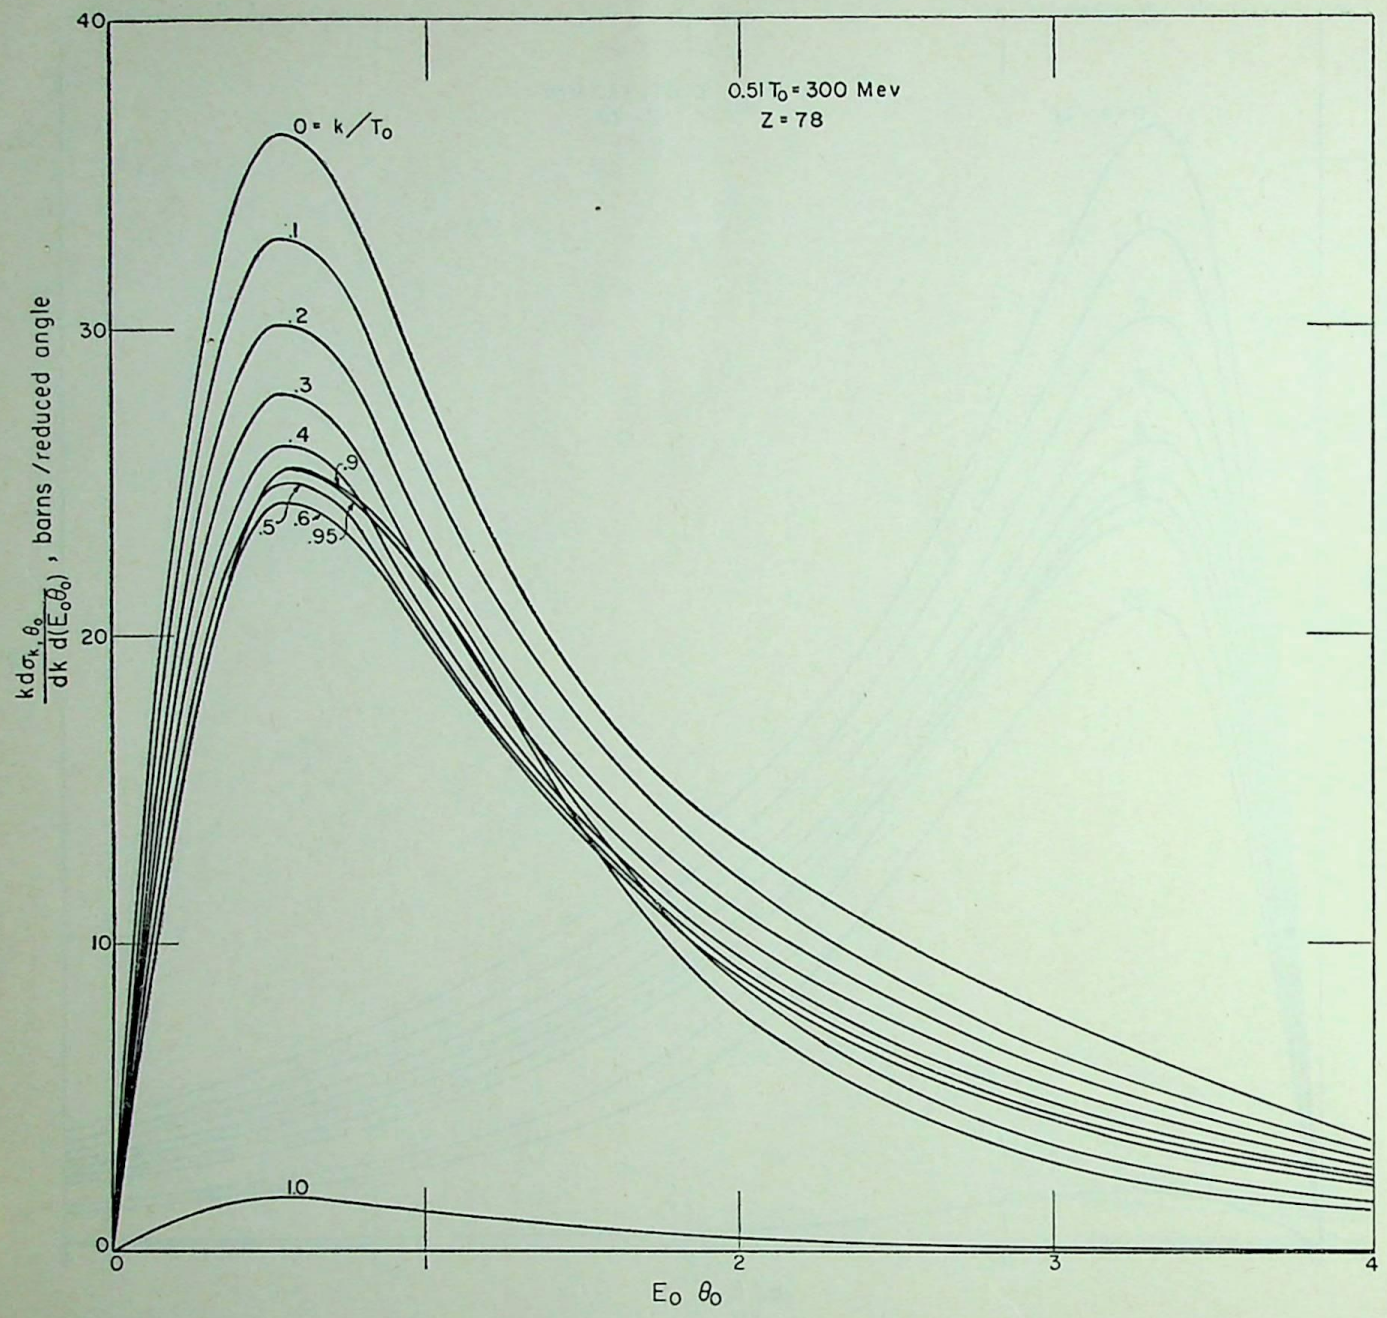

FIG. 6(e)

lines give the Thomas-Fermi atomic radii for beryllium and gold. A comparison of r_{max} with r_{TF} shows that r_{max} is larger than r_{TF} at low and high energies. To be specific, screening effects can be expected to become important over a large part of the spectrum for electron kinetic energies above approximately 5 Mev and below approximately 10 kev. For low fractional photon energies where $k \leq 0.1T_0$, screening effects are important for all values of T_0. It is interesting to observe that for the high photon energies the screening effects are the least important for values of T_0 approximately equal to the electron rest energy.

The accuracy obtainable with a bremsstrahlung formula corrected for screening depends on the validity of the extreme-relativistic approximations and on the adequacy of the atomic model used to provide the form factor. Only the latter will be commented on here. The most extensive calculations and applications have been based on the Thomas-Fermi atomic model. However, the Hartree self-consistent field model is more accurate[24] but more difficult to apply. The atomic form factors predicted by the two models have been compared by Nelms and Oppenheim[24] and are given in Fig. 14. The curves in this figure show that the accuracy of the Thomas-Fermi model decreases as the atomic number decreases.

Information concerning the influence of the form factor differences on the bremsstrahlung cross section can be obtained by referring to pair production calculations. The nuclear momentum distribution in the pair production process at extreme-relativistic energies as calculated by Jost, Luttinger, and Slotnik,[25] is given in Fig. 15. Their results show that the most probable q values are of the order of 0.1. Table IV gives the ratio of the Thomas-Fermi to the Hartree form factors for representative q values, as obtained by Nelms and

Oppenheim[24] for carbon and mercury. These differences produce different estimates for the pair production cross section: for example at 60 Mev, the cross section for carbon with the Hartree form factor is increased by $\frac{1}{2}\%$ above the cross section calculated with the Thomas-Fermi form factor.[26] Comparable detailed information is not available for the bremsstrahlung process. However, general conclusions are possible on the basis of a comparison of the maximum impact parameters for bremsstrahlung and pair production. The maximum impact parameter for bremsstrahlung is $(2E_0E/k)$ and the similar expression for pair production is $(2E_+E_-/k)$ where E_+ and E_- are the total energies of the positron and electron. By varying the values of E and k for fixed E_0 in bremsstrahlung and the values of E_+ and E_- for fixed k in pair production, we find that the important impact parameters in bremsstrahlung are larger on the average than those in pair production. This fact explains why the screening effect is much larger on ϕ_{rad} than on ϕ_{pair} for equal values of E_0 and k (see, for example, the total cross sections for the two processes in reference 9, pp. 252 and 262). The larger screening effect indicates that the use of the Hartree form factor

in place of the Thomas-Fermi factor will have a greater effect on ϕ_{rad} than on ϕ_{pair}.

The first detailed study of the influence of form factors on screened bremsstrahlung cross sections was made by Bethe.[27] Bethe's calculations, which are summarized in the formulas of Tables I and II, consider four types of screening:

1, complete screening condition: $\gamma \approx 0$;
2, intermediate screening condition I: $\gamma < 2$;
3, intermediate screening condition II: $2 < \gamma < 15$;
4, no screening condition: $\gamma \gg 1$.

The Bethe[27] and Bethe-Heitler[28] screening calculations with intermediate conditions I and II were performed numerically using the tabulations of the atomic form factor for the Thomas-Fermi model given by Bethe.[29]

In the work of Schiff[14] analytical calculations were made possible by the use of the complete screening condition ($\gamma \approx 0$) and an approximate screened atom potential, V, given by $(Ze/r)\exp(-r/a)$, where $a = (111/Z^{\frac{1}{3}})$. The atomic form factor, $F_e(q,Z)$, corresponding to this potential is given by the quantity $[1+(aq)^2]^{-1}$. For many purposes the Schiff Formulas 2BS and 3BS(e) are sufficiently accurate. Schiff[14] notes that compared to the intermediate screening Formula 3BS, the complete-screening Formula 3BS(e), "is larger than it should by by less than 2% for moderate values of Z and is never more than 4% high in the worst case of large Z and energies such that screening is incomplete."

A third procedure for including form factor effects was developed by Moliére.[30] By approximating the Thomas-Fermi potential with a simple analytical expression, he obtained the following relation:

$$\frac{[1-F_e(q,Z)]}{q^2} = \sum_{i=1}^{3} \frac{\alpha_i}{\beta_i^2+q^2}, \qquad \text{(II-12)}$$

where $\alpha_1 = 0.10$, $\alpha_2 = 0.55$, $\alpha_3 = 0.35$,

$$\beta_i = Z^{\frac{1}{3}} b_i/121; \quad b_1 = 6.0, \quad b_2 = 1.20, \quad b_3 = 0.30.$$

The Moliére function has been applied by Olsen and Maximon[8] to obtain intermediate screening formulas that include Coulomb corrections.

The most accurate predictions of screening corrections to bremsstrahlung cross sections for specific target elements can be obtained by the use of the Hartree form factors in the formulas that permit the use of arbitrary form factors, e.g., Formulas 3BS(b) and 2CS(b). Unfortunately, the screening corrections for these formulas must be evaluated numerically and are not as convenient to use as the complete screening formulas just discussed.

F. Comparison of Theory and Experiment

Very few experimental determinations of the bremsstrahlung cross section are available for comparison with the estimates given in Secs. IIC, D, and E. At present, experimental data on cross sections have been obtained for electron kinetic energies of 34 kev[31] by Amrehn[32] and Röss,[32] 50 kev by Motz and Placious,[33] 90 to 180 kev by Mausbeck[34] and Zeh,[34] 0.5 and 1.0 Mev by Motz,[35] and 2.72, 4.54, and 9.66 Mev by

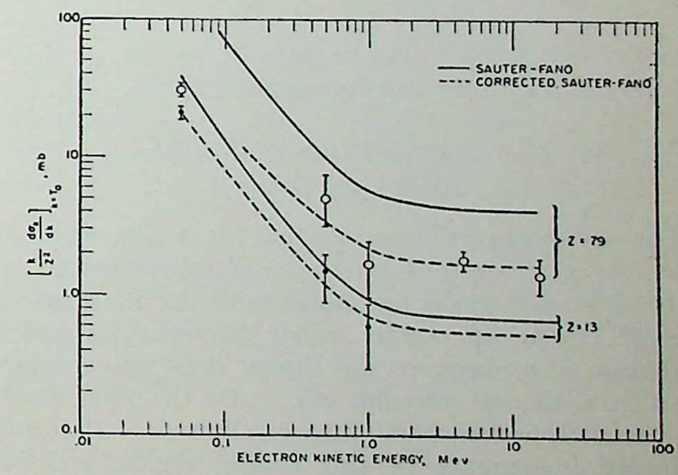

FIG. 12. Dependence of the bremsstrahlung cross section at the high-frequency limit, integrated over photon direction, on the incident electron kinetic energy. These data are obtained from reference 21, and the dashed curves are estimated to give the most accurate values for the cross section.

[31] Most of the experimental data that is available in this low-energy region has been produced by the pioneering work of Kulenkampff and co-workers. Their measurements give extensive information about relative angular distributions and spectra from thin targets, and show general agreement with the nonrelativistic Sommerfeld theory.[5] The details of their various results are not included in this report which is primarily concerned with absolute cross-section measurements and comparisons with the Born-approximation theory.

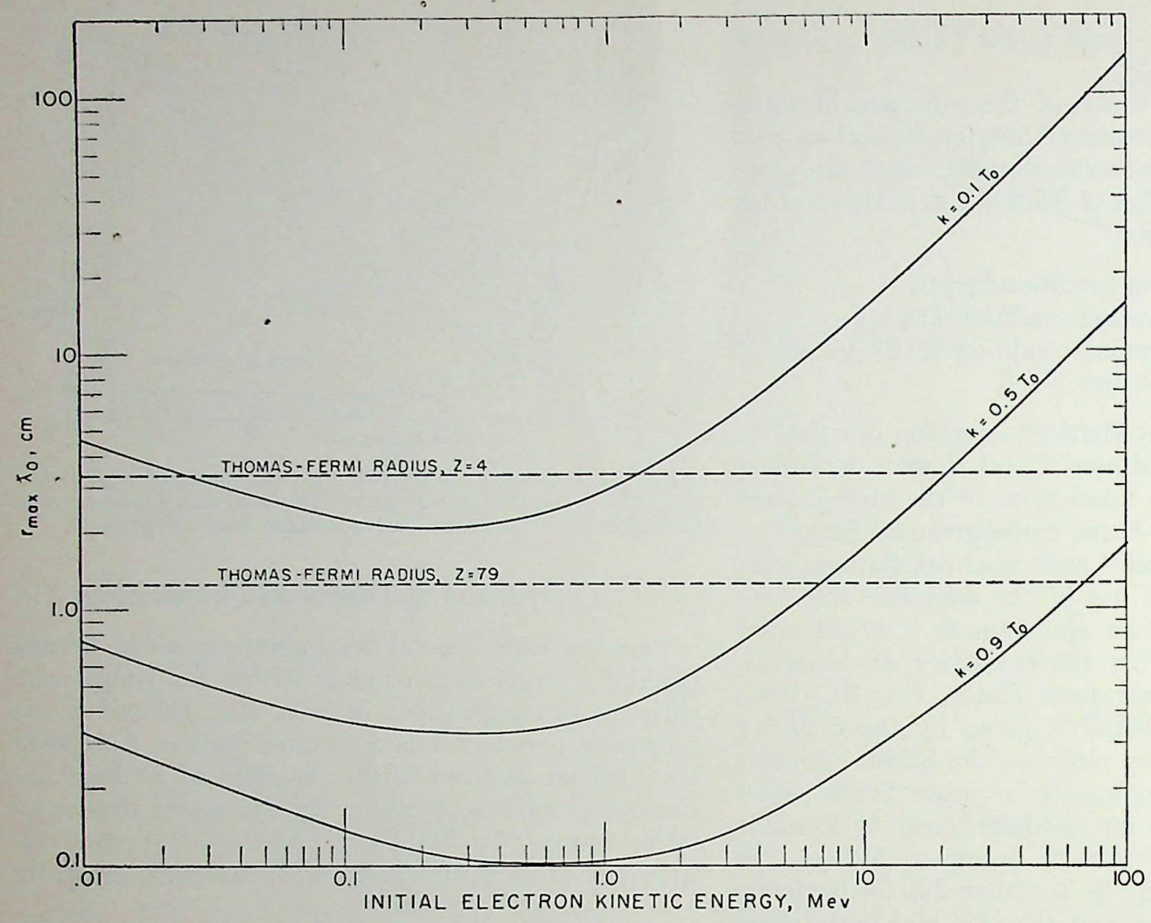

FIG. 13. Dependence of r_{max} on the initial electron kinetic energy for k equal to $0.1T_0$, $0.5T_0$, and $0.9T_0$. r_{max} is the reciprocal of the minimum momentum transferred to the nucleus ($=p_0-p-k$), and is given in units of the Compton wavelength, λ_0. The dashed lines give the values of the Thomas-Fermi radius ($=137Z^{-\frac{1}{3}}$) for beryllium and gold.

Starfelt and Koch.[36] The important results of these studies are combined and summarized below.

(1) *Cross-Section Differential in Photon Energy and Angle*

For electron kinetic energies that are small compared with the electron rest energy, the experimental results[31–33] show general agreement with the Sommerfeld theory[5] except for certain minor discrepancies which probably occur because the theory does not account for relativistic and screening effects. On the other hand, the Born-approximation theory (Formula 2BN) is seriously inadequate in this energy region and no analytical correction factors for the Born-approximation formula are available in this differential form. Furthermore, no quantitative studies are available on the importance of screening.

For electron kinetic energies that are of the same order of magnitude as the electron rest energy, the Born-approximation theory (Formula 2BN) underestimates the experimental cross section[34,35] as shown by the comparison in Fig. 16. These data also show that the differences between the theory and experiment increase with (a) the photon energy, (b) the photon angle, and (c) the atomic number of the target.

For electron kinetic energies that are large compared with the electron rest energy, the experimental results[36] agree within 10% with the Born-approximation theory. For example, in Fig. 17, the experimental cross sections for gold at 4.54 Mev[36] show general agreement with the predictions of the screened, extreme-relativistic Schiff Formula 2BS and of the unscreened Sauter Formula 2BN. There are differences in detail (generally less than 10% in this energy region): (a) near the high-frequency limit, the experimental cross sections are greater than the Schiff cross sections which in turn are greater than the Sauter cross sections; (b) in the low-frequency region, the experimental cross sections show good agreement with the Schiff cross sections, but are less than the unscreened Sauter cross sections. For low Z targets, there is better agreement with the Sauter formula.

(2) *Cross-Section Differential in Photon Energy*

A comparison[21] of experimental and theoretical values for the cross section differential in photon energy, $d\sigma_k$, is given in Figs. 18–21 for electron energies of 0.05, 0.5, 1.0, and 4.5 Mev. Each of these figures gives the estimates of (a) the Born-approximation cross sections [Formulas 3BN or 3BN(a)]; (b) the corrected Sauter-Fano cross sections at the high-frequency limit [Sec. IIE(2)]; (c) the Elwert-Born approximation cross sections [Sec. IIE(1)]; and (d) the experimental results. The solid lines show the cross sections computed from Formula 3BN(a) for 0.05 Mev, and Formula 3BN for

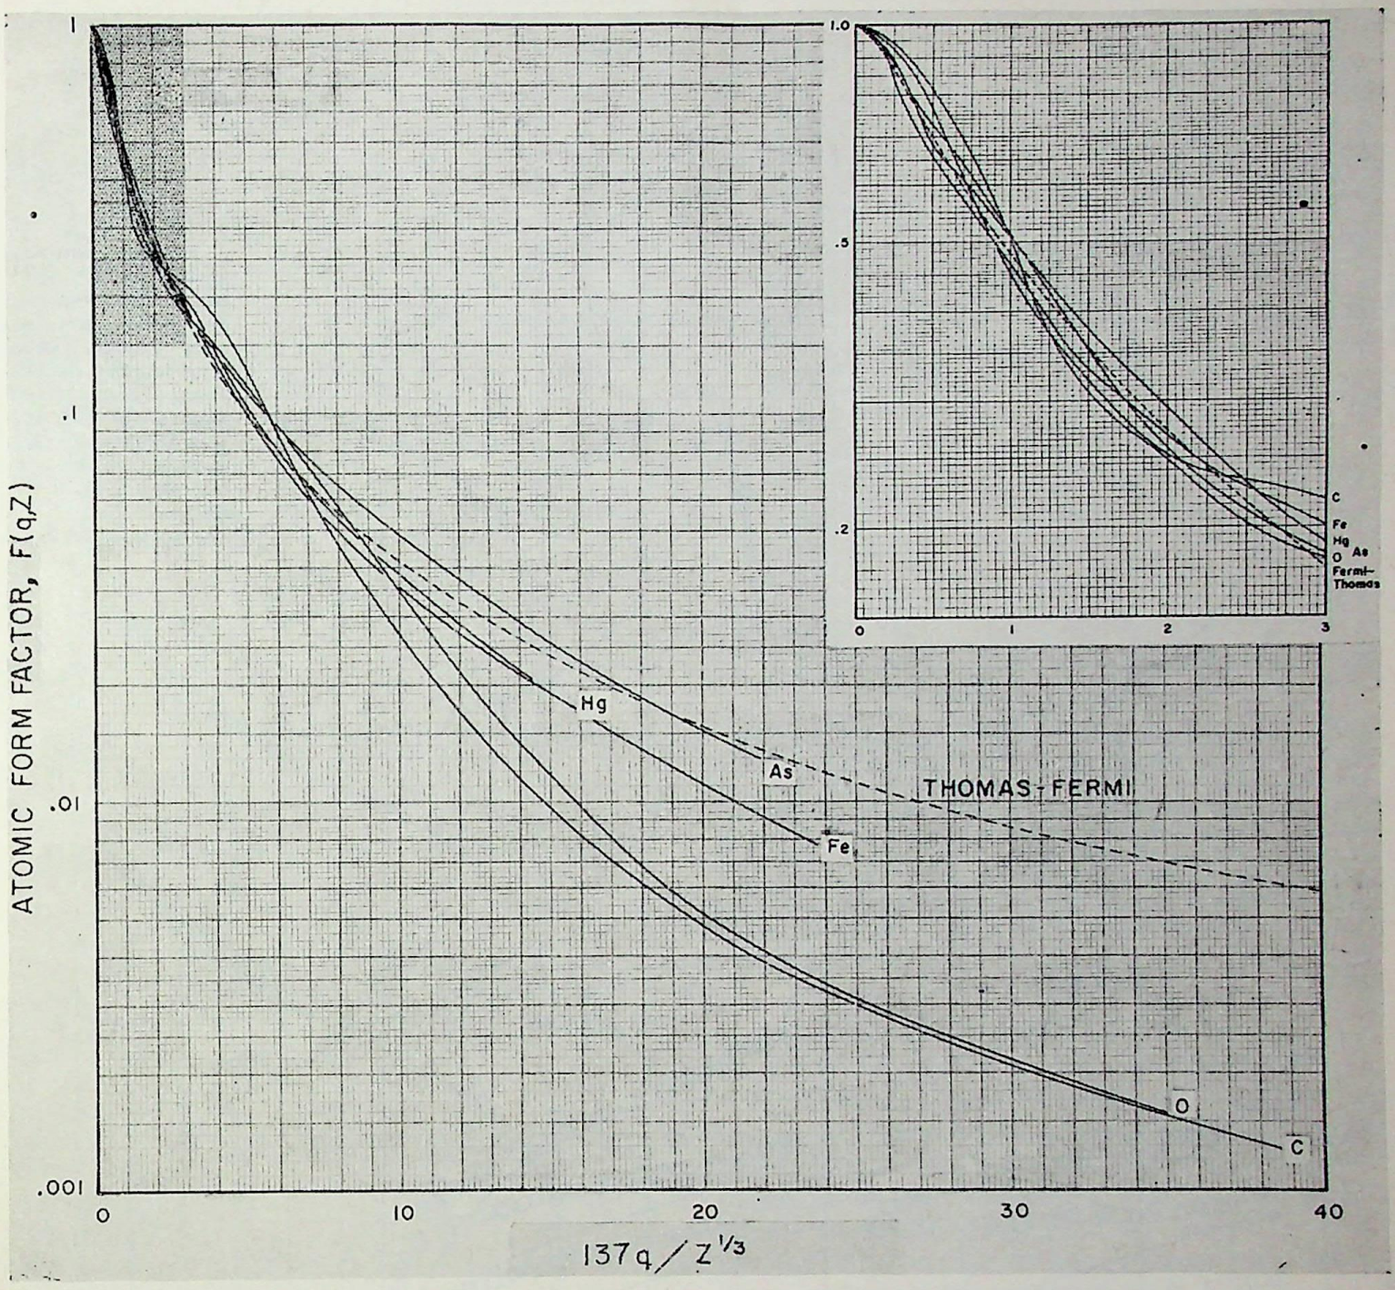

FIG. 14. Evaluation[24] of the atomic form factor, $F(q,Z)$, for the Hartree self-consistent field model (solid lines) and for the Thomas-Fermi model (dashed line), as a function of the nuclear momentum transfer, q.

0.5, 1, and 4.5 Mev. The dashed lines give the Born-approximation cross sections corrected by the Elwert factor defined in Formula (II-4). The comparison with the experimental results shows that the Elwert correction gives the most accurate results at very low energies (below 0.1 Mev). For electron kinetic energies of the order of the electron rest energy, the cross sections obtained with the Elwert correction factor are still less than the experimental values (by as much as a factor of two in the worst case). For very high energies, the Born-approximation theory overestimates the actual cross sections, and the Elwert factor is no longer valid, although it gives good agreement with experiment in the 5-Mev cross-over region [see Sec. IIF(3)]. The corrected Sauter-Fano cross sections at the high-frequency limit show good agreement with the experimental results as noted previously in Fig. 12.

(3) *Total Cross Section*

The experimental values for the total cross section, ϕ_{rad} (defined in Sec. IIC), are shown in Fig. 22 by the closed and open circles for initial electron kinetic energies of 0.05 Mev,[33] 0.5 Mev,[35] and 1.0 Mev.[35] The theoretical values are shown by the solid lines, which are predicted by Formulas 4BN(a) in the region where $T_0 \leq 0.5$ and by Formula 4BN for no screening. The curves that include screening corrections for $Z=13$ and 79 are obtained by numerical integration of the intermediate screening Formulas 3BS(c) and 3BS(d). For

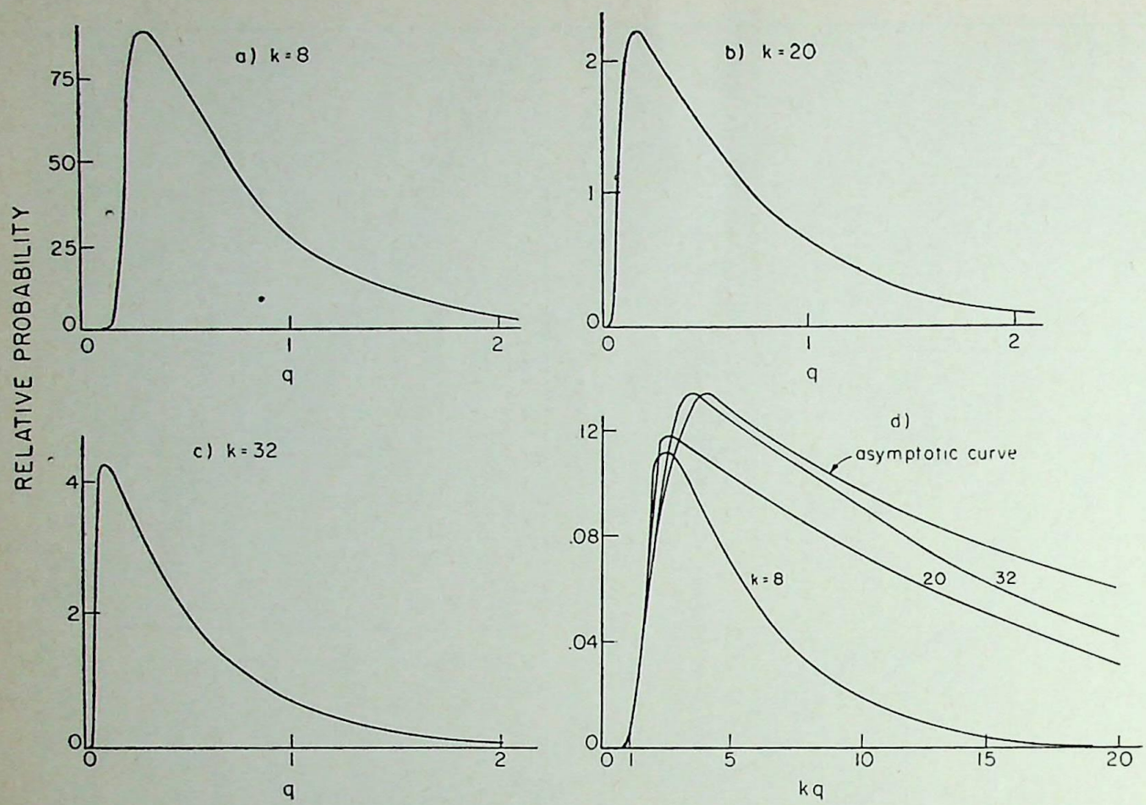

FIG. 15. Momentum distributions[25] for the recoil nucleus in nuclear pair production for several photon energies. The relative number of recoils are plotted in Figs. 15(a), (b), and (c) as a function of the momentum, q. These curves are summarized in (d) and are compared with the asymptotic curve.

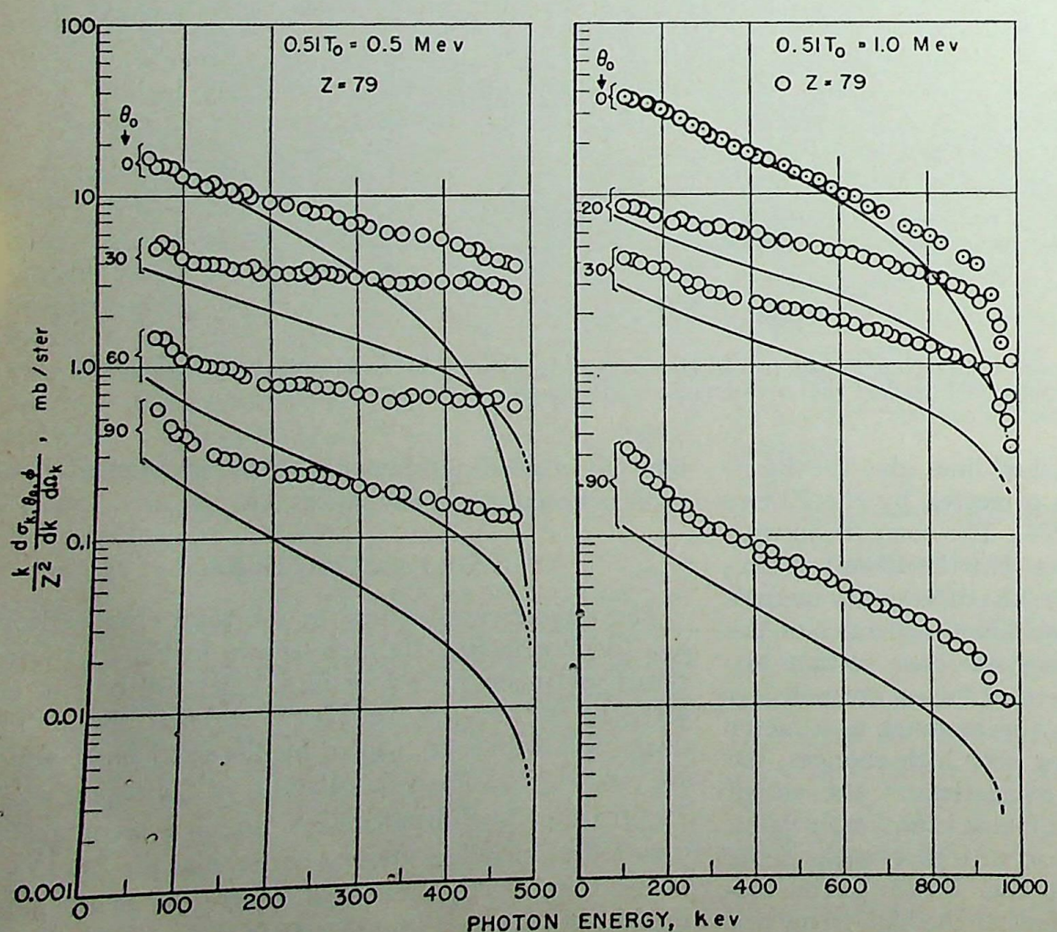

FIG. 16. Dependence of the bremsstrahlung cross section $d\sigma k,\theta_0,\phi$ on photon energy and angle, θ_0, for 0.5- and 1.0-Mev electrons. The theoretical cross sections shown by the solid curves are calculated from Formula 2BN, and the experimental values[35] for gold are given by the open circles.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

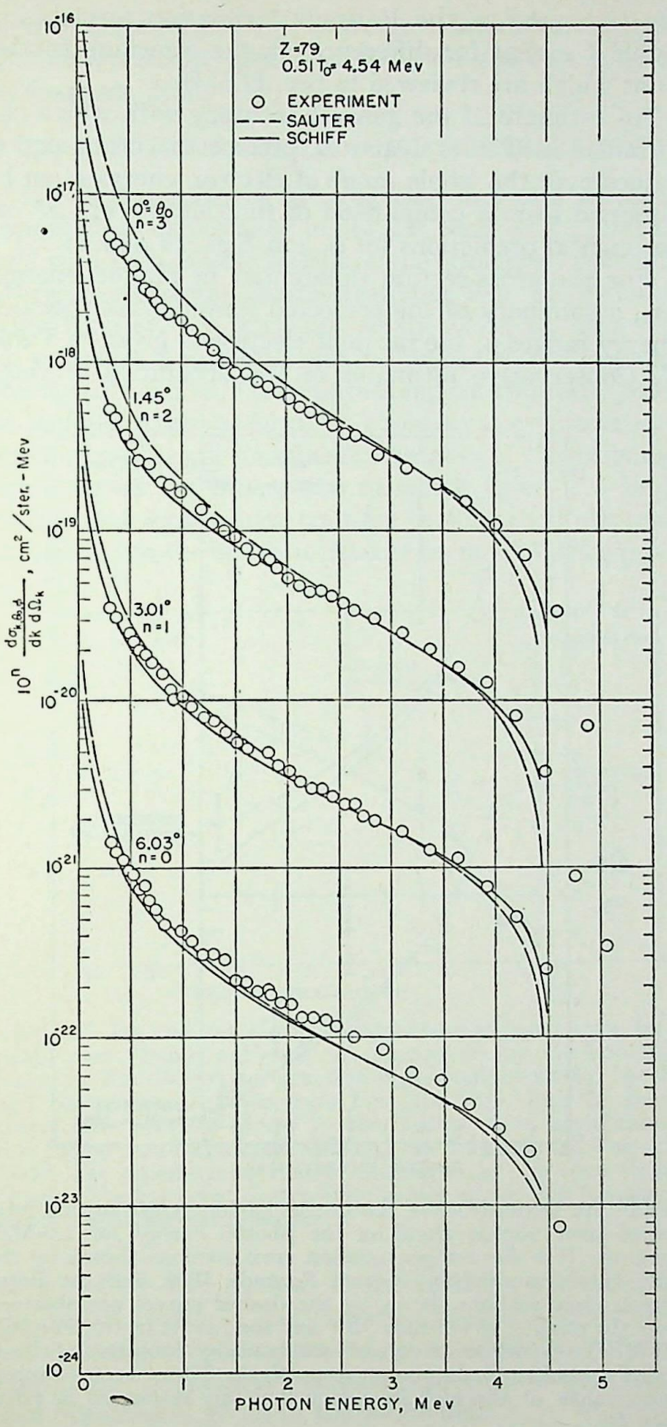

FIG. 17. Dependence of the bremsstrahlung cross section $d\sigma_{k,\theta_0,\phi}$ for gold, on the photon energy and angle, θ_0, for 4.54-Mev electrons. The theoretical cross sections are given by the solid curve (Schiff, Formula 2BS), and by the dashed curve (Sauter, Formula 2BN). The experimental values[36] for gold are given by the open circles.

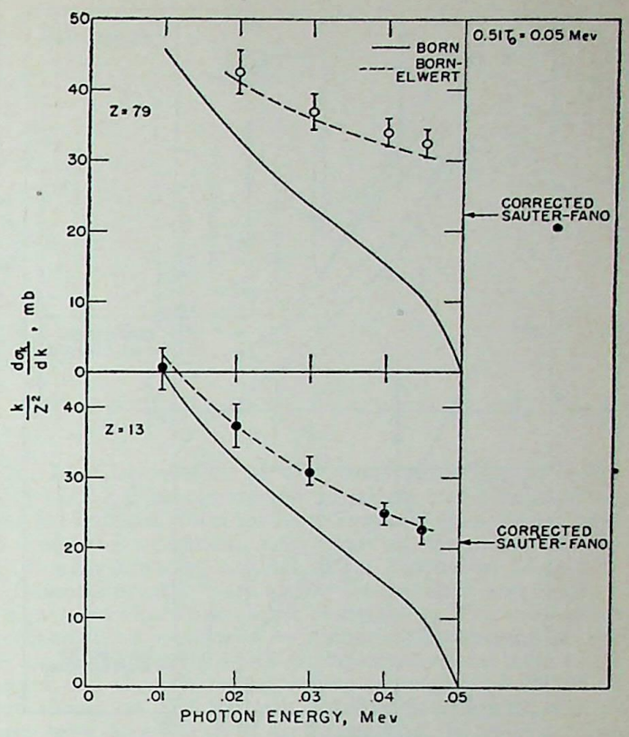

FIG. 18. Dependence of the bremsstrahlung cross section integrated over photon angle on the photon energy for 0.05-Mev electrons. The Born-approximation cross sections shown by the solid curves are calculated from Formula 3BN(a), and the Born-Elwert cross sections shown by the dashed curves are obtained from the product of Formula 3BN(a) and the Elwert factor, Formula (II-4). The experimental values[33] are shown by the open and closed circles for gold and aluminum, respectively. The corrected Sauter-Fano values at the high-frequency limit are estimated in reference 21.

extreme-relativistic energies, the triangles give the most accurate theoretical cross-section values[37] for $Z=79$, which are estimated by numerical integration of the Coulomb-corrected Formula 3CS. The most accurate values for ϕ_{rad}, which are estimated from the above combined data, are shown by the dashed curve for $Z=13$ and the dot-dashed curve for $Z=79$.

Approximate correction factors for the Born-approximation ϕ_{rad} values with screening have been estimated as a function of the initial electron kinetic energy from the ratios of the cross-section values shown in Fig. 22 by the empirical (dashed and dot-dashed) curves and by the Born-approximation curves with screening. These estimated factors are given in Fig. 23, and show that the ratios are equal to unity at the energy of approximately 10 Mev for aluminum and 6 Mev for gold. For energies larger than these crossover energies, the Born-approximation formula overestimates the cross section; for smaller energies, the reverse is true. Even though the correction factor for ϕ_{rad} may be close to unity for a given electron energy, much larger (or smaller) correction factors may be required for the differential cross section, $d\sigma_k$, in the high- or low-frequency region because of a crossover effect (see Fig. 39 in Bethe and Salpeter, reference 1), which is masked by the integration of $d\sigma_k$. It is interesting to observe in Fig. 23, that the maximum correction factor for the Born-approximation calculations occurs at electron kinetic energies approximately equal to the electron rest energy.

[37] For $Z=13$, the corrected values for energies above 50 Mev have only small differences (less than one percent) with the values shown by the solid line for $Z=13$.

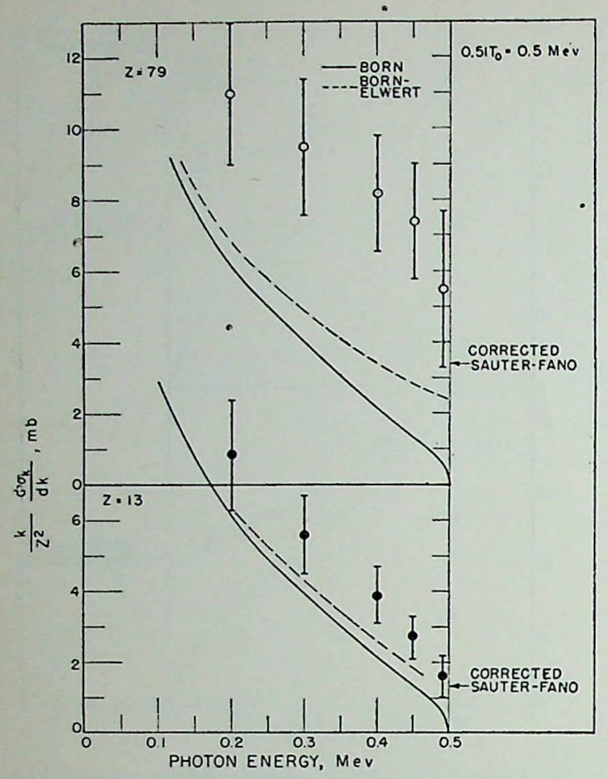

FIG. 19. Dependence of the bremsstrahlung cross section integrated over photon angle on the photon energy for 0.5-Mev electrons. The Born-approximation cross sections shown by the solid curves are calculated from Formula 3BN, and the Born-Elwert cross sections shown by the dashed curves are obtained from the product of Formula 3BN and the Elwert factor, Formula (II-4). The experimental values[35] are shown by the open and closed circles for gold and aluminum, respectively. The corrected Sauter-Fano values at the high-frequency limit are estimated in reference 21.

G. Summary

A survey of the foregoing data leads to some general conclusions about the accuracy of the cross-section values predicted by the various formulas and correction factors. Also, suggestions can be made for selecting formulas that give the best estimates for the cross section or that can be easily evaluated to give reasonably accurate results. These judgments are summarized in the following.

In Table I, the screened formulas depend on the extreme-relativistic approximation and therefore are valid only in the energy region $T_0 \gg 1$. For $T_0 \ll 1$, only the nonscreened formulas are applicable.[38] The nonscreened formulas require relatively large correction factors except in the region near the crossover energy (see Fig. 22). At the extreme relativistic energies the nonscreened formulas are less accurate than the screened formulas.

In Table II, the extreme-relativistic cross section formulas for $d\sigma_{k,\theta_0,\phi}$ and $d\sigma_k$ are estimated to have an accuracy that is given approximately by the factor $(Z/137)^2(\ln E/E)$. For $f(Z)=0$, the formulas in Table II are the same as the Born-approximation formulas in Table I except for differences in the screening corrections which are reviewed in Sec. IIE(3).

An estimate of the general accuracy with which the formulas in Tables I and II predict the cross-section values over the whole range of electron energies can be obtained from a comparison of the theoretical and experimental predictions for ϕ_{rad} in Figs. 22 and 23.

For the cross-section differential in photon energy, $d\sigma_k$, a summary of the corrected formulas for specified energy ranges of the incident electron is given in Table V. Conservative estimates of the accuracies of these formulas have been made on the basis of the experimental data assembled in this report. The greatest uncertainties are in the energy range from 0.10 to 2.0 Mev. Because of the uncertainties of screening effects, no corrected formulas are given for the energy region below 0.1 Mev. These corrected formulas are tentative and it can be expected that some will be replaced by more accurate expressions as more data becomes available.

For the cross-section formulas differential in photon energy and angle, $d\sigma_{k,\theta_0,\phi}$, no quantitative corrections are available for low and intermediate energies because

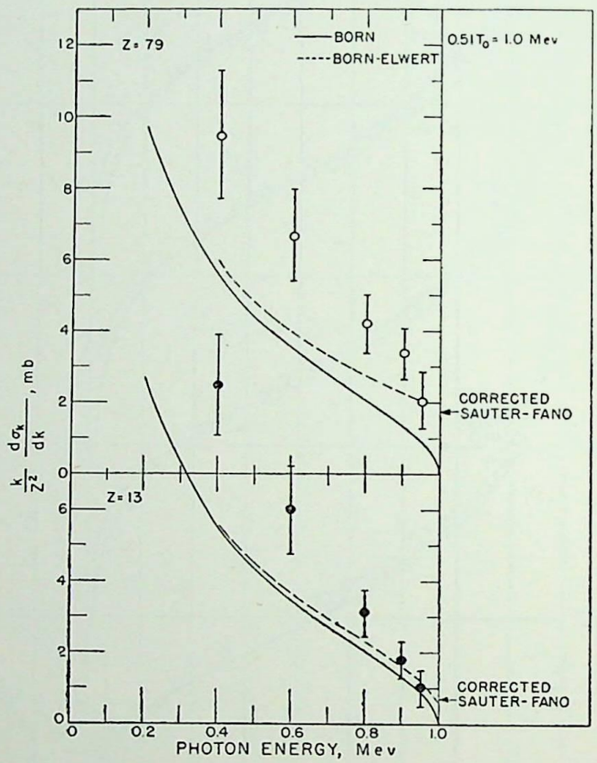

FIG. 20. Dependence of the bremsstrahlung cross section integrated over photon angle on the photon energy for 1.0-Mev electrons. The Born-approximation cross sections shown by the solid curves are calculated from Formula 3BN, and the Born-Elwert cross sections shown by the dashed curves are obtained from the product of Formula 3BN and the Elwert factor, Formula (II-4). The experimental values[35] are shown by the open and closed circles for gold and aluminum, respectively. The corrected Sauter-Fano values at the high-frequency limit are estimated in reference 21.

[38] A Born-approximation formula that includes screening effects without the extreme-relativistic approximation, has been given by Gluckstern and Hull, Phys. Rev. 90, 1030 (1953). This formula applies mainly to the low-frequency region and has been found to be inadequate[36] in the high-frequency region.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

of insufficient data. For extreme relativistic energies, the most accurate estimates (3%) for $d\sigma_{k,\theta_0\phi}$ are given by Formula 2CS.

III. ELECTRON-ELECTRON BREMSSTRAHLUNG

The bremsstrahlung cross-section formulas for electron-nuclear interactions in Sec. IIC vary as Z^2. For targets with high atomic numbers, the additional influence of electron-electron bremsstrahlung can be included approximately by replacing Z^2 by $Z(Z+1)$. However for very low Z elements such as hydrogen or beryllium, the electron-electron bremsstrahlung contributions must be included more accurately. Cross-section calculations for this process are complicated because of the exchange character of the interaction in which there is a large energy and momentum transfer to the recoil electron, in contrast to the electron-nuclear bremsstrahlung process in which the nucleus is assumed to be infinitely heavy. No complete calculations are available for predicting the detailed features of electron-electron bremsstrahlung.[39] A summary of pertinent results that have been obtained is given in the following.

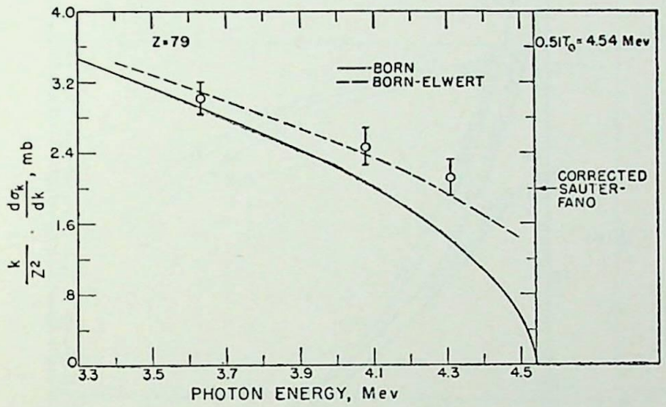

FIG. 21. Dependence of the bremsstrahlung cross section integrated over photon angle on the photon energy for 4.54-Mev electrons. The Born-approximation cross sections shown by the solid curve are calculated from Formula 3BN, and the Born-Elwert cross sections shown by the dashed curve are obtained from the product of Formula 3BN and the Elwert factor, Formula (II-4). The experimental values[36] are shown by the open circles for gold. The corrected Sauter-Fano values at the high-frequency limit are estimated in reference 21.

A. Maximum Photon Energy

In the electron-electron bremsstrahlung process, the maximum photon energy that is available in the laboratory system at the laboratory angle θ_0 is[35]

$$k_{\max}=F/(1-\sqrt{F}\cos\theta_0), \qquad \text{(III-1)}$$

where F is equal to $(E_0-1)/(E_0+1)$. Table VI gives some values of $k_{\max}$ at zero and 90 degrees obtained from Formula (III-1) for various incident electron kinetic energies. From the very sparse experimental information[35,36] available on electron-electron bremsstrahlung, some results[35] have shown reasonably good agreement with the values of $k_{\max}$ predicted by Formula (III-1).

[39] For a general review of the available theories on electron-electron bremsstrahlung, see J. Joseph and F. Rohrlich, Revs. Modern Phys. **30**, 354 (1958).

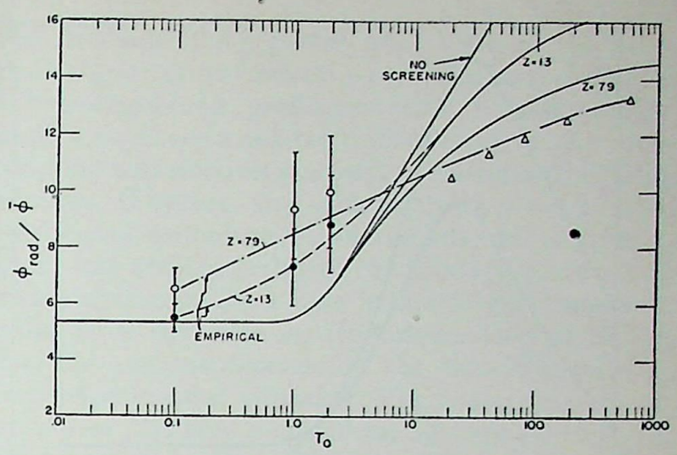

FIG. 22. Dependence of the total radiation cross section, $\phi_{\rm rad}[=(1/E_0)\int_0^{T_0}k d\sigma_k]$, on the initial electron kinetic energy, T_0. The solid lines are obtained from Formula 4BN for no screening, and from the numerical integration of Formulas 3BS(c) and 3BS(d) with screening corrections for Z equal to 13 and 79. The experimental points[33,35] are shown by the open and closed circles for a gold and aluminum target, respectively. The values shown by the triangles are estimated by numerical integration of Formula 3CS for $Z=79$. On the basis of the experimental data at the low energies and the theoretical values (triangles) predicted by the exact theory at the extreme relativistic energies, the dashed curves have been drawn as an estimate of the most accurate $\phi_{\rm rad}$ values for Z equal to 13 and 79.

B. Cross-Section Formulas for Free Electrons

(1) *Nonrelativistic Energies*

In contrast to the electron-nucleus and electron-positron systems, the electron-electron system has no

TABLE V. Corrected cross-section formulas for $d\sigma_k$.

Kinetic energy range for incident electron, Mev	Corrected cross-section formula[a]	Restrictions	Estimated accuracy[b]
0.01–0.10	$d\sigma_k=f_E d\sigma_k^{3BN(a)}$	$k>0.01T_0$	±5%
0.10–2.0	$d\sigma_k=Af_E d\sigma_k^{3BN}$	$k>0.01T_0$	±20%
2.0–15	$d\sigma_k=Ad\sigma_k^{3BN}$	$\gamma>15$	b
	$=Ad\sigma_k^{3BS(d)}$	$2<\gamma<15$	±5%
	$=Ad\sigma_k^{3BS(c)}$	$\gamma<2$	±5%
15–50	$d\sigma_k=d\sigma_k^{3BN}$	$\gamma>15$	b
	$=Ad\sigma_k^{3BS(d)}$	$2<\gamma<15$	±3%
	$=Ad\sigma_k^{3BS(c)}$	$\gamma<2$	±3%
50–500	$d\sigma_k=d\sigma_k^{3BN}$	$\gamma>15$	b
	$=d\sigma_k^{3CS(a)}$	$2<\gamma<15$	±3%
	$=d\sigma_k^{3CS(b)}$	$\gamma<2$	±3%

where f_E is defined in Formula (II-6), A is the correction factor given in Fig. 23, γ is equal to the quantity $100k(E_0EZ^{\frac{1}{2}})^{-1}$.

[a] The superscripts for $d\sigma_k$ give the formula numbers defined in Sec. IIC.
[b] No estimated accuracy is given at photon energies near the high-frequency limit of the spectrum. If better accuracy is desired in this region, the cross section at the high-frequency limit can be obtained from the dashed curves in Fig. 12, and the spectrum shape may be adjusted by fitting this end to the curves given by the formulas in column 2 above.

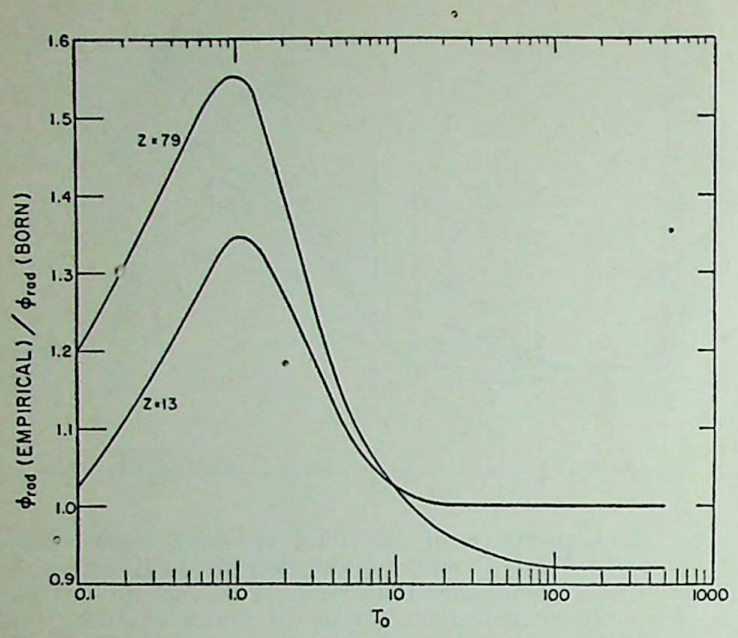

FIG. 23. Approximate correction factors for the Born-approximation ϕ_{rad} values with screening shown in Fig. 22. These factors have been estimated from the ratios of the empirical (dashed and dot-dashed) curves to the Born-approximation curves with screening in Fig. 22.

dipole moment. Therefore the electron-electron bremsstrahlung cross section becomes zero for calculations based only on the nonrelativistic dipole approximation. Garibyan[40] has made calculations beyond the dipole approximation and has obtained the following nonvanishing result for the cross-section differential in photon energy:

$$d\sigma_k'=\frac{r_0^2Z}{137}\left(\frac{8}{15}\frac{\beta}{\beta_0^3}\frac{dk}{k}\right)\left[17-\frac{3(\beta_0^2-\beta^2)^2}{(\beta_0^2+\beta^2)^2}+\left(\frac{\beta_0^2+\beta^2}{\beta_0\beta}+26\frac{\beta_0\beta}{\beta_0^2+\beta^2}-\frac{24\beta_0^3\beta^3}{(\beta_0^2+\beta^2)^3}\right)\times\ln\left(\frac{\beta_0+\beta}{\beta_0-\beta}\right)\right], \quad \text{(III-2)}$$

which for $k\rightarrow 0$ becomes[39]

$$d\sigma_{k\rightarrow 0}'=\frac{r_0^2Z}{137}\left[\frac{32}{5}\frac{dk}{k}\frac{1}{\beta_0^2}\left(\ln\frac{4\beta_0^2}{k}+\frac{17}{12}\right)\right]. \quad \text{(III-3)}$$

These results are only valid for $T_0\ll 1$.

TABLE VI. Maximum photon energy for electron-electron bremsstrahlung.

T_0	k_{max} $\theta_0=0°$	$\theta_0=90°$
100	99.	0.98
10	9.7	0.83
1.0	0.79	0.33
0.1	0.069	0.048
0.01	0.0054	0.0050

[40] G. M. Garibyan, Zhur. Eksptl. i Teoret. Fiz. 24, 617 (1953).

(2) *Extreme-Relativistic Energies*

Several calculations[39] based on the extreme-relativistic approximations give the following approximate formula for the cross-section differential in photon energy:

$$d\sigma_k'=\frac{4r_0^2Z}{137}\frac{dk}{k}\left[\left(1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right)\times\left(\ln\frac{2E_0E}{k}-\frac{3}{2}\right)-\frac{E_0E}{9}\right], \quad \text{(III-4)}$$

which is similar in form to the electron-nuclear cross-section Formula 3BN(b).

The total radiation cross section obtained from Formula (III-4) is given as

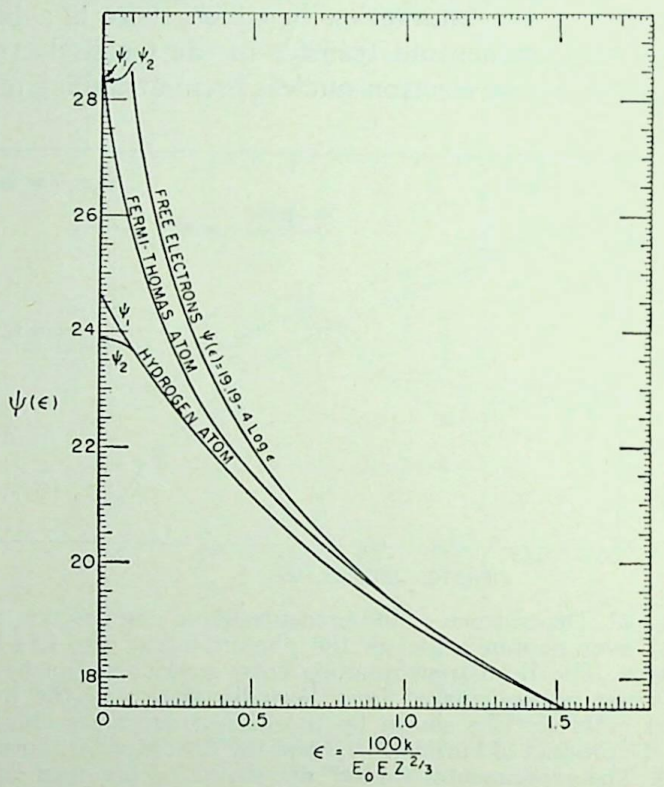

FIG. 24. Screening factors,[41] ψ_1 and ψ_2, for electron-electron bremsstrahlung. The curve marked "Hydrogen atom" was calculated[41] with exact wave functions. For free electrons, $\psi_1=\psi_2=\psi$.

$$\phi_{rad}'=\frac{4r_0^2Z}{137}[\ln(2E_0)-\tfrac{4}{3}]. \quad \text{(III-5)}$$

C. Cross-Section Formulas with Binding Corrections

The influence of atomic binding on the electron-electron bremsstrahlung cross section has been calculated only in the extreme-relativistic approximation. With the Thomas-Fermi model, the corrected formula for the cross-section differential in photon energy is[39]

$$d\sigma_k'=\frac{4r_0^2Z}{137}\frac{dk}{k}\left[\left(1+\left(\frac{E}{E_0}\right)^2\right)(\tfrac{1}{4}\psi_1(\epsilon)-1-\ln Z^{\frac{2}{3}})-\frac{2}{3}\frac{E}{E_0}(\tfrac{1}{4}\psi_2(\epsilon)-\tfrac{5}{6}-\ln Z^{\frac{2}{3}})\right], \quad \text{(III-6)}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where ϵ is equal to $100k(E_0EZ^{\frac{1}{3}})^{-1}$, and ψ_1 and ψ_2 are given[41] by the data in Fig. 24. For complete screening where $\epsilon \sim 0$, the cross section becomes

$$d\sigma_k' = \frac{4r_0^2Z}{137}\frac{dk}{k}\left(1+\left(\frac{E}{E_0}\right)^2-\frac{2}{3}\frac{E}{E_0}\right)\ln\frac{530}{Z^{\frac{1}{3}}}. \quad \text{(III-7)}$$

The total radiation cross section which is obtained for the complete screening case from (III-7) is given by

$$\phi_{\text{rad}}' = (4r_0^2Z/137)\ln(530/Z^{\frac{1}{3}}). \quad \text{(III-8)}$$

A comparison of this Formula (III-8) with the electron-nuclear bremsstrahlung cross-section Formula 4BS shows that the Z electrons in an atom increase the electron-nuclear cross section by the factor η so that the total cross section becomes

$$\phi_{\text{rad}}{}^{\text{total}} = Z(Z+\eta)(\phi_{\text{rad}}{}^{\text{4BS}}/Z^2). \quad \text{(III-9)}$$

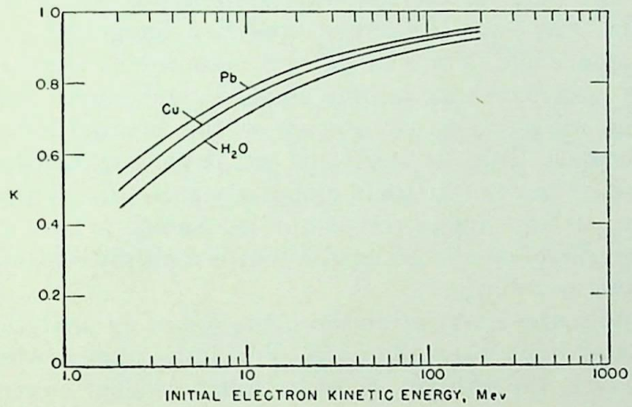

FIG. 25. Dependence of the radiation probability correction factor, $K(=\phi_{\text{rad}}/\phi_{\text{rad}}{}^*)$, on the initial electron kinetic energy and the target atomic number.

For complete screening, η is given by

$$\eta = \ln\frac{530}{Z^{\frac{1}{3}}}\Big/\left(\ln\frac{183}{Z^{\frac{1}{3}}}+\frac{1}{18}\right), \quad \text{(III-10)}$$

which varies from 1.04 for magnesium to 0.88 for lead. For most cases, a value of η equal to unity is sufficiently accurate.

IV. THICK-TARGET BREMSSTRAHLUNG PRODUCTION

Bremsstrahlung is produced in *thick* targets for most practical cases. In this discussion, a target is defined to be *thick* if the scattering and energy loss processes that occur as the electrons traverse the target have an appreciable influence on the bremsstrahlung production. In principle, a complete description of the bremsstrahlung emitted from a given target can be obtained from the cross sections for the pertinent elementary processes. For example, the angular distribution of the total bremsstrahlung power, the shape of the bremsstrahlung spectrum from an x-ray tube, or the efficiency of bremsstrahlung production can be calculated if detailed data are available with regard to the bremsstrahlung and electron scattering (elastic and inelastic) processes. However, any such analysis is necessarily a complicated procedure, since the calculations for the energy loss and scattering of the primary electrons and the absorption of the x-rays in the target must be included with the cross-section information of Sec. II. Also, the analysis depends on the characteristics of a given experimental situation. For these reasons, this paper does not give a complete, systematic treatment of thick-target bremsstrahlung production; instead it is confined to the presentation of pertinent experimental data as well as useful analytical results and procedures. Also, emphasis is placed on thick-target results that give absolute data on photon intensities and bremsstrahlung production efficiencies.

Some of the analytical results for thick-target bremsstrahlung are most conveniently expressed in terms of certain quantities which are defined in the following discussion. When an electron traverses a target, the average energy lost in the path length element dx by radiation can be written as

$$-dE_0 = NE_0(K\phi_{\text{rad}}{}^*)dx = KE_0dt, \quad \text{(IV-1)}$$

where N is the number of target atoms per cm^3 and $K\phi_{\text{rad}}{}^*$ is equal to the cross section ϕ_{rad} defined in Sec. IIC. $\phi_{\text{rad}}{}^*$ is equal to $(4Z^2r_0^2/137)\ln(183Z^{-\frac{1}{3}})$ cm^2, which is approximately the same as the expression for ϕ_{rad} at extreme-relativistic energies (see Formula 4BS). K is defined as the radiation probability correction factor and is plotted in Fig. 25 for various values of the target atomic number and the electron kinetic energy. The length t is given in units of the radiation length, t_0, which is defined as

$$t_0 = 1/N\phi_{\text{rad}}{}^* \text{ cm}. \quad \text{(IV-2)}$$

Values for t_0 in units of g/cm^2 as a function of the target atomic number are plotted in Fig. 26.

A. Thick-Target Bremsstrahlung Angular Distributions

(1) *Nonrelativistic and Intermediate Energies*[42]

For electron energies that are small or comparable to the electron rest energy, no analytical or empirical formulas have been derived for estimating the bremsstrahlung angular distribution from thick targets, and only a few experimental results are available.

In contrast to the extreme-relativistic region, the radiation intensity produced at these low energies is

[41] J. A. Wheeler and W. E. Lamb, Phys. Rev. **55**, 858 (1939), and **101**, 1836 (1956).

[42] The results that are presented for the nonrelativistic and intermediate energy region where $T_0 \leq 1$ apply only to targets that are thick enough to stop the electrons. For the relativistic region where $T_0 \gg 1$, there is no such restriction on the target thickness.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

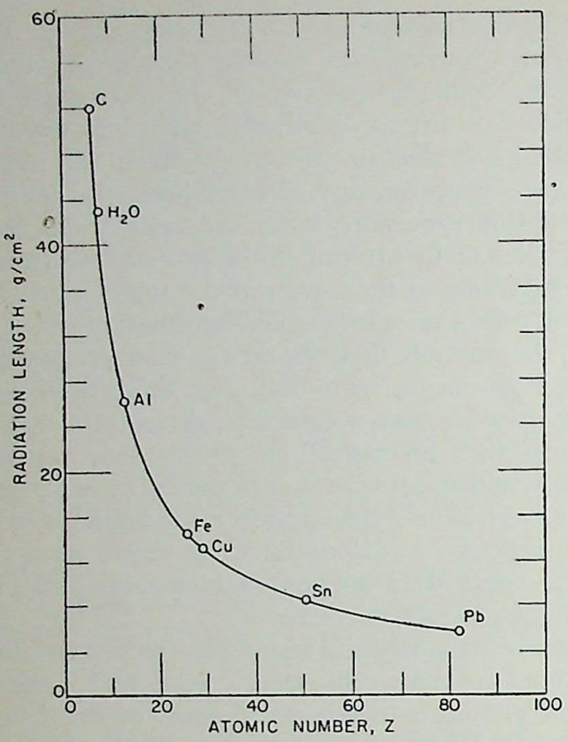

FIG. 26. Radiation lengths in grams per square centimeter for various materials.

important at large angles, and is about the same order of magnitude at both zero and ninety degrees. However, because the absorption of the bremsstrahlung photons in the target is large, the angular distribution of the bremsstrahlung is largely dependent on the target geometry in specific experimental situations. One of the few examples in which angular distribution data are presented in a more general way with corrections for the geometry and the target absorption is to be found in the measurements of Buechner, Van de Graaff, Burrill, and Sperduto[43] for initial electron kinetic energies in the region from 1.25 to 2.35 Mev. Their results for beryllium and gold targets are given in Fig. 27. The curves show the angular dependence of the radiation intensity integrated over photon energy for specified electron energies. These data indicate that the intensity ratio at zero and ninety degrees is approximately 10 for beryllium and 3 for gold at 1.5 Mev, and approximately 40 for beryllium and 4 for gold at 2.35 Mev. Also from these data, we can obtain the following empirical expressions for the power radiated at zero degrees:

$$I_{(\alpha=0)}(\mathrm{Au}) = 9.4(\mathcal{T}_0)^{2.9} \text{ roentgens per minute per ma at 1 meter for gold,}$$
$$I_{(\alpha=0)}(\mathrm{Be}) = 0.92(\mathcal{T}_0)^{3.4} \text{ roentgens per minute per ma at 1 meter for beryllium,} \quad \text{(IV-3)}$$

where $\mathcal{T}_0$ is the electron kinetic energy in m_0c^2 units for the electrons incident on the target, and α is the angle between the photon direction and the direction of the incident electron beam. Then with the approximate conversion factor of one roentgen equal to 3000 ± 500 ergs/cm^2 for photons with energies in the range from 0.1 to 2 Mev,[44] we have

$$I_{(\alpha=0)}(\mathrm{Au}) = 0.5(\mathcal{T}_0)^{2.9} \text{ watts/ma-steradian,}$$
$$I_{(\alpha=0)}(\mathrm{Be}) = 0.05(\mathcal{T}_0)^{3.4} \text{ watts/ma-steradian.} \quad \text{(IV-4)}$$

From these equations, the fraction, R, of the total incident electron kinetic energy that is radiated per steradian at zero degrees is

$$R_{(\alpha=0)}(\mathrm{Au}) = 10^{-3}(\mathcal{T}_0)^{1.9} \text{ for gold,}$$
and
$$R_{(\alpha=0)}(\mathrm{Be}) = 10^{-4}(\mathcal{T}_0)^{2.4} \text{ for beryllium.} \quad \text{(IV-5)}$$

(2) *Relativistic Energies*

At high energies, estimates of the bremsstrahlung angular distribution from thick targets have been made on the basis of the following simplifying approximations. First, the thin-target spectrum integrated over photon angle (Formula 3BS) is assumed to represent the spectrum shape for any angle. Second, the intrinsic (thin target) angular spread of the bremsstrahlung (Formula 2BS) is neglected at large angles where $\alpha \gg E_0^{-1}$ but not at small angles where $\alpha \leq E_0^{-1}$; therefore, at large angles the photon is assumed to have the same direction as the electron that is multiply scattered before it radiates.

With these approximations, the following analytical results have been obtained. For large angles where $\alpha \gg E_0^{-1}$, the fraction, R, of the total incident electron

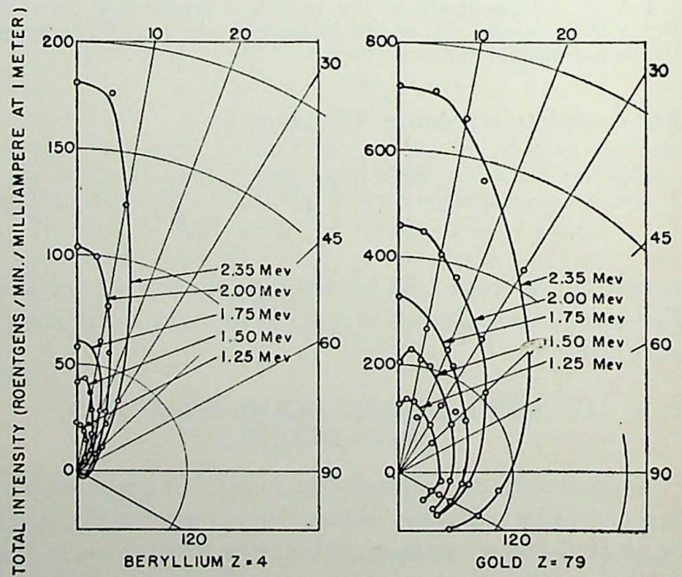

FIG. 27. Angular dependence of the thick-target bremsstrahlung intensity integrated over photon energy for 1.25- to 2.35-Mev electrons. These results were obtained by Buechner, Van de Graaff, Burrill, and Sperduto[43] and include corrections for the target.

[43] Buechner, Van de Graaff, Burrill, and Sperduto, Phys. Rev. 74, 1348 (1948).

[44] W. V. Mayneord, Brit. J. Radiol. Suppl. No. 2, 136 (1950). For photons outside this energy range, the conversion factor has a significant energy dependence and the factor must be weighted by the bremsstrahlung spectrum shape.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

kinetic energy that is radiated per steradian at the angle, α, is given[45] as

$$R_{(\alpha \gg E_0^{-1})} = \frac{K\mathcal{E}_0^2}{1760\pi} \mathrm{Ei}\left[\frac{-\mathcal{E}_0^2\alpha^2}{1760t}\right], \qquad \text{(IV-6)}$$

where $\mathcal{E}_0$ is the total energy in m_0c^2 units of the electron incident on the target, and Ei is the exponential integral[46]

$$-\mathrm{Ei}(-y) = \int_y^\infty \frac{e^{-z}}{z} dz, \quad >0 \text{ for } y>0. \qquad \text{(IV-7)}$$

For small angles where $\alpha \lesssim E_0^{-1}$, Muirhead, Spicer, and Lichtblau[47] have obtained the following expression for the bremsstrahlung angular distribution

$$R_{(\alpha \lesssim E_0^{-1})} = \frac{K\mathcal{E}_0^2}{1760\pi}\left\{-\mathrm{Ei}\left[\frac{-\mathcal{E}_0^2\alpha^2}{1760t}\right] + \mathrm{Ei}\left[\frac{-\mathcal{E}_0^2\alpha^2}{7.15}\right]\right\}. \qquad \text{(IV-8)}$$

This formula gives good agreement with experimental data[47] and can readily be evaluated at small angles by keeping the first term in the expansion of the exponential integrals which is

$$\mathrm{Ei}(-z_1) - \mathrm{Ei}(-z_2) \rightarrow \ln(z_1/z_2) \quad \text{for} \quad z_1, z_2 \rightarrow 0. \qquad \text{(IV-9)}$$

Thus

$$R_{(\alpha=0)} = \frac{K\mathcal{E}_0^2}{1760\pi} \ln 246t, \text{ for } t \gg 2\times10^{-3}. \qquad \text{(IV-10)}$$

For $t=0.1$ and $\mathcal{E}_0=3$, this formula agrees reasonably well with the result predicted by the low-energy Formula (IV-5). For thin targets, this "on-axis" intensity becomes[45]

$$R_{(\alpha=0)} = Kt\mathcal{E}_0^2/4\pi, \quad \text{for} \quad t \ll 2\times10^{-3}. \qquad \text{(IV-11)}$$

Estimates of the ratio $R_\alpha/R_{(\alpha=0)}$ for tungsten ($Z=74$) are given in Fig. 28 for three target thicknesses.

Several conclusions for high-energy angular distributions can be drawn from the form of the Formulas (IV-8), (IV-10), and (IV-11). The logarithmic form of Formula (IV-10) shows that most of the radiation comes from the front part of the target. Also, since the fractional energy radiated depends on $\mathcal{E}_0^2$, the total energy radiated at zero degrees will depend on $\mathcal{E}_0^3$. Two additional effects influence the dependence on $\mathcal{E}_0$ of the total radiated energy. The factor K, according to Fig. 25, increases slightly with $\mathcal{E}_0$, and for very thick targets the effective t in Formula (IV-10) will increase logarithmically with $\mathcal{E}_0$. Therefore, the total energy radiated on the axis of the bremsstrahlung beam will depend on at least a 3.2 exponent for a thin target and on a slightly higher exponent for a thick target. The specific exponent to be used will depend on the energy range of interest, the effective target thickness, and the experimental geometry.

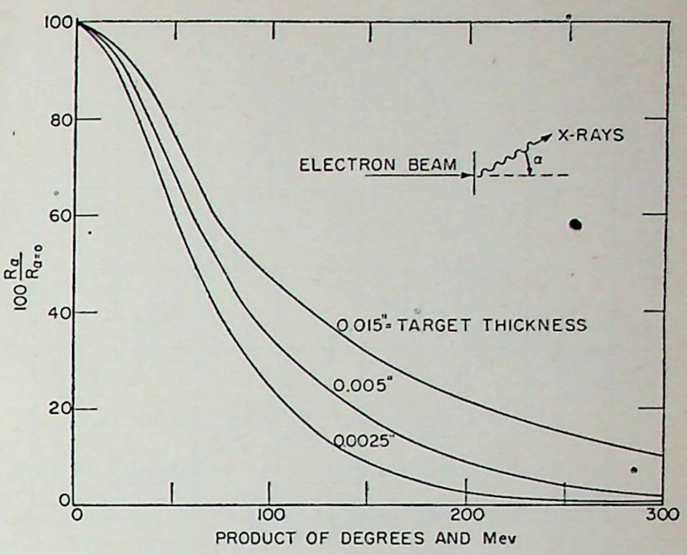

FIG. 28. Theoretical bremsstrahlung angular distributions from thick tungsten targets for relativistic energies. These data are obtained from the National Bureau of Standards Handbook 55. R_α is defined as the fraction of the total incident electron kinetic energy that is radiated per steradian at the angle α.

B. Thick-Target Bremsstrahlung Spectra

(1) *Nonrelativistic and Intermediate Energies*[42]

In this low-energy region the radiation has a broad angular distribution (see IVA), and the dependence of the spectrum shape on photon angle is important.[48] No general analytical expressions which accurately predict the spectrum as a function of angle for any experimental situation are available at these energies. Part of the difficulty has been the inadequacy of the Born-approximation cross-section differential in photon energy and angle (Formula 2BN). Nevertheless it has been possible to obtain reasonable agreement between theoretical and experimental thick-target spectrum shapes shown in Fig. 29 for a particular application[49] with an initial electron kinetic energy of 1.4 Mev, photon angles of zero and ninety degrees, and a tungsten target. In this example, the experimental results confirm the theoretical dependence of the spectrum shape on photon angle after distortions due to photon absorption in the target and surrounding materials are eliminated. The results also show that the relative number of photons in the high-frequency region increases as the emission angle becomes smaller. This trend is just opposite to the behavior observed for thin-target spectra.[35]

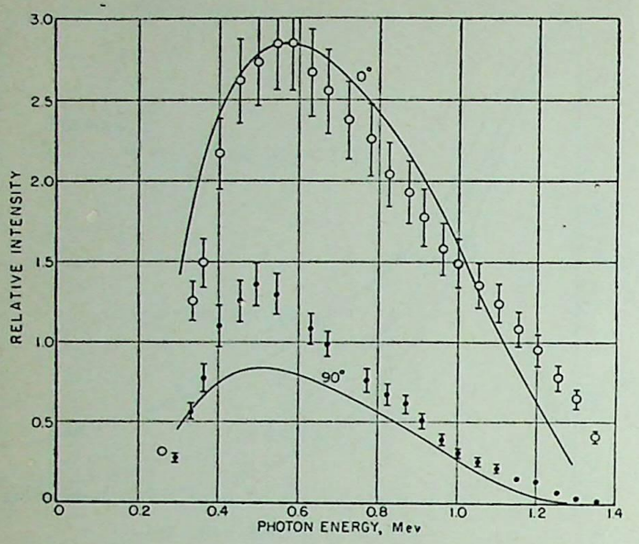

FIG. 29. Relative spectral intensities at 0° and 90° for 1.4-Mev electrons incident on a thick-tungsten target.[49] The solid curves are obtained from theoretical estimates that include electron scattering effects and photon absorption in the materials surrounding the target. The experimental values have been normalized and are shown by the open (zero degrees) and closed (90 degrees) circles. To obtain absolute spectral intensities in Mev per steradian per Mev per incident electron, the ordinate should be multiplied by 10^{-3} for the theoretical curves and by 2.1×10^{-3} for the experimental points.

With regard to estimates of the shape of the spectrum integrated over the photon direction, Kramers[50] obtained the following simple, analytical expression:

$$I_k = AZ(k_0-k), \qquad \text{(IV-12)}$$

where I_k is the energy radiated in all directions in the energy interval, $(k, k+dk)$, A is a proportionality constant, and k_0 is the photon energy at the high-frequency limit. This result was derived on the basis of a nonrelativistic, semiclassical calculation, in which electron scattering effects (including backscattering) were neglected and only the electron energy loss was considered. In spite of these limitations and because of its simplicity, the Kramers Formula (IV-12) has been used extensively to estimate the thick-target spectrum (not including the characteristic radiation[51]) at a given angle for various experimental cases, with corrections included for the photon absorption in the target and surrounding materials. Results obtained for various electron energies in this low-energy region have shown general qualitative agreement between the theoretical (Kramers) and experimental spectrum shapes,[52] and indicate that Formula (IV-12) is satisfactory, at least for order of magnitude estimates.

(2) *Relativistic Energies*[42]

Two complementary procedures for calculating thick-target spectra at high energies which include effects of electron scattering in the target are given by Penfold[53] and Hisdal.[54] The Penfold calculations estimate the thick-target effects primarily in the high-frequency region and give the spectrum integrated over photon directions up to a maximum angle, Γ, with respect to the direction of the incident electron beam. The Hisdal calculations estimate the thick-target effects on the over-all spectrum shape in the forward direction and should not be applied to the high-frequency region.

The Penfold method[53,55] assumes that (a) the Schiff Formula 3BS(e) describes the intrinsic spectrum at all angles; (b) the electron energy loss rather than electron scattering in the target produces the predominant effect on the shape of the spectrum for large values of Γ; (c) no electron radiates more than one photon; and (d) the photon absorption in the target is negligible. With these approximations, Penfold obtained the following formula for the thick-target spectrum integrated over photon direction to a maximum angle Γ determined by the detector:

$$P_k = nN_0\int_{k+1}^{\mathcal{E}_0} S(\mathcal{E}_0,E_0,\Gamma,x_0)\,d\sigma_k\,dE_0, \qquad \text{(IV-13)}$$

where P_k is the number of photons in the energy interval k to $k+dk$, N_0 is the number of target atoms per cm^3, n is the number of electrons incident on the target, $\mathcal{E}_0$ is the total energy of the incident electron in m_0c^2 units, x_0 is the target thickness in g/cm^2, and $d\sigma_k$ is given by Formula 3BS(e) for electrons with energy E_0. The function S represents the probability that radiation produced by the electrons reaches the detector, and can be written as

$$S(\mathcal{E}_0,E_0,\Gamma,x_0) = \int_0^{x_0} B_3(\mathcal{E}_0,E_0,\Gamma,x)B_4(\Gamma,E_0,x)B_5(x_0,x)\,dx, \qquad \text{(IV-14)}$$

where the function B_3 gives the fraction of the radiation emitted by electrons with energy E_0 at the target depth x, B_4 is the fraction of electrons that penetrate beyond the thickness x, and B_5 accounts for path length straggling. These B functions require involved numerical evaluations, and the results are described in detail in the Penfold report.[53] Motz, Miller, and Wyckoff[56] have estimated the thick-target spectrum for a particular experimental situation in which the brems-

[55] A similar but less general method has been used by R. Wilson, Proc. Phys. Soc. (London) **A66**, 038 (1953). Wilson's calculations did not include electron scattering effects in the target and his results give a spectrum shape averaged over the photon directions.
[56] Motz, Miller, and Wyckoff, Phys. Rev. **89**, 968 (1953).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

strahlung is produced with an 11.3 Mev (kinetic energy) electron beam incident on a tungsten target (approximately 0.010-inch thick), and is measured on the beam axis with a small detector ($\Gamma\sim 0$). They used the following simplified, analytical form for the thick-target generating function:

$$S=1-\exp\left\{-\frac{1}{51(\mathcal{E}_0-E_0)}\left(\frac{\mathcal{E}_0}{E_0}\right)^2\right\} \qquad \text{(IV-15)}$$

and, as shown in Fig. 30, have obtained good agreement with experimental results. For the more general calculations, Penfold used Formulas (IV-13) and (IV-14) to estimate the thick-target spectrum shapes for an incident electron kinetic energy of 15 Mev, a 0.020-inch platinum target, and for two detectors which subtend different angles on the electron beam axis, ($\Gamma=10$ degrees, $\Gamma\gg 10$ degrees). A comparison is made in Fig. 31 of these two Penfold results (curves C and D) with the spectrum shape predicted by Formula 3BS(e) (curve A) and with the shape resulting from the application of the S function in Formula (IV-15) (curve B). The curves show that Formulas 3BS(e) and (IV-15) give a greater number of photons in the high-frequency region relative to the total number in the spectrum compared with the more accurate spectral shape predicted by the Penfold procedure. For certain cases, the spectrum shape predicted by the simplified Formula (IV-15) may be sufficiently accurate.

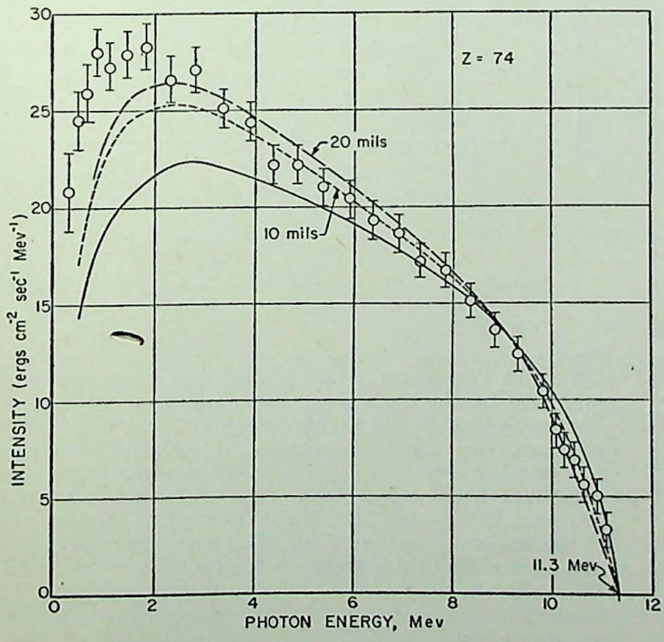

FIG. 30. Bremsstrahlung intensity spectrum in the forward direction for 11-Mev electrons incident on a thick-tungsten target.[56] The thin-target Born spectrum, modified by the photon absorption in the materials surrounding the target, is shown by the solid curve. The dashed curves show the spectra expected for a 10-mil and a 20-mil target, and the experimental values are given by the open circles.

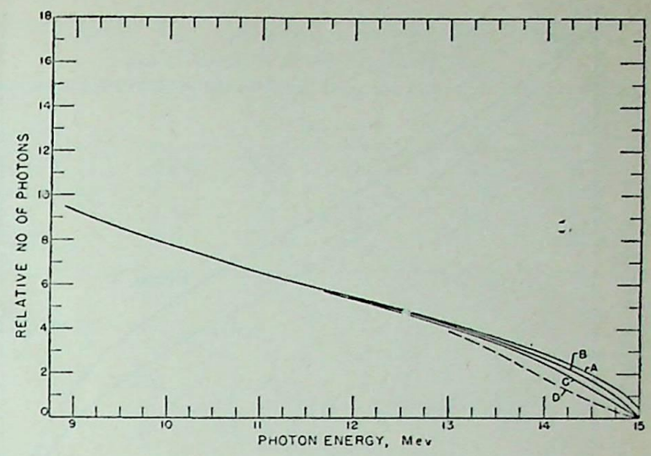

FIG. 31. Comparison of the spectrum shapes predicted by the thick target Penfold calculations[53] and by Schiff's thin target Formula 3BS(e) for 15-Mev electrons. The Schiff curve A shows the spectrum integrated over photon angle. Curve B is the spectrum shape predicted by Formula (IV-13) with the simplified S function given by Formula (IV-15). Curve C is the spectrum shape predicted by the Penfold calculations [Formulas (IV-13) and (IV-14)] for a 0.020-in. platinum target and a detector which subtends an angle, Γ, of 10 degrees. Curve D gives the Penfold spectrum for $\Gamma\gg 10$ degrees.

The Hisdal method[57] assumes that (a) the spectrum variation with angle as given by the Schiff Formula 2BS has the dominant effect on the thick-target spectrum shape; (b) the energy loss of electrons in the target is negligible; (c) no electron radiates more than one photon; and (d) the photon absorption in the target is negligible. With these approximations, Hisdal has calculated tables for estimating the spectrum shape to be expected in a small detector placed on the electron beam-target axis. Hisdal's results are given in terms of a correction factor which multiplies Formula 3BS(e) for a given value of k to obtain the corrected spectrum for a particular target thickness. Examples of spectra calculated by Hisdal's method are given in Figs. 32(a)–(e) for 10-, 20-, 40-, 90-, and 300-Mev electrons, and are compared with the Schiff spectra integrated over photon direction [Formula 3BS(e)]. When the detector subtends a large solid angle at the target, the measured spectrum shape is given by the cross section integrated over the photon direction. Figures 7 and 8 give data for the spectrum shape included within a given detector angle. If this shape for a given experimental arrangement is estimated to be similar to the zero degree spectrum, then the Hisdal correction will be important; if this shape is estimated to be more similar to the spectrum integrated over all angles, then Hisdal's correction will be unimportant.

C. Efficiency for Bremsstrahlung Production

The bremsstrahlung production efficiency for a given electron kinetic energy and target material is defined

[57] Similar calculations that apply only to a specific target material and electron energy have been made by A. Sirlin, Phys. Rev. **106**, 637 (1957). While the Hisdal calculations include only the Schiff complete screening approximations, Sirlin examined the effects of both the intermediate and complete screening approximations on the spectrum shape.

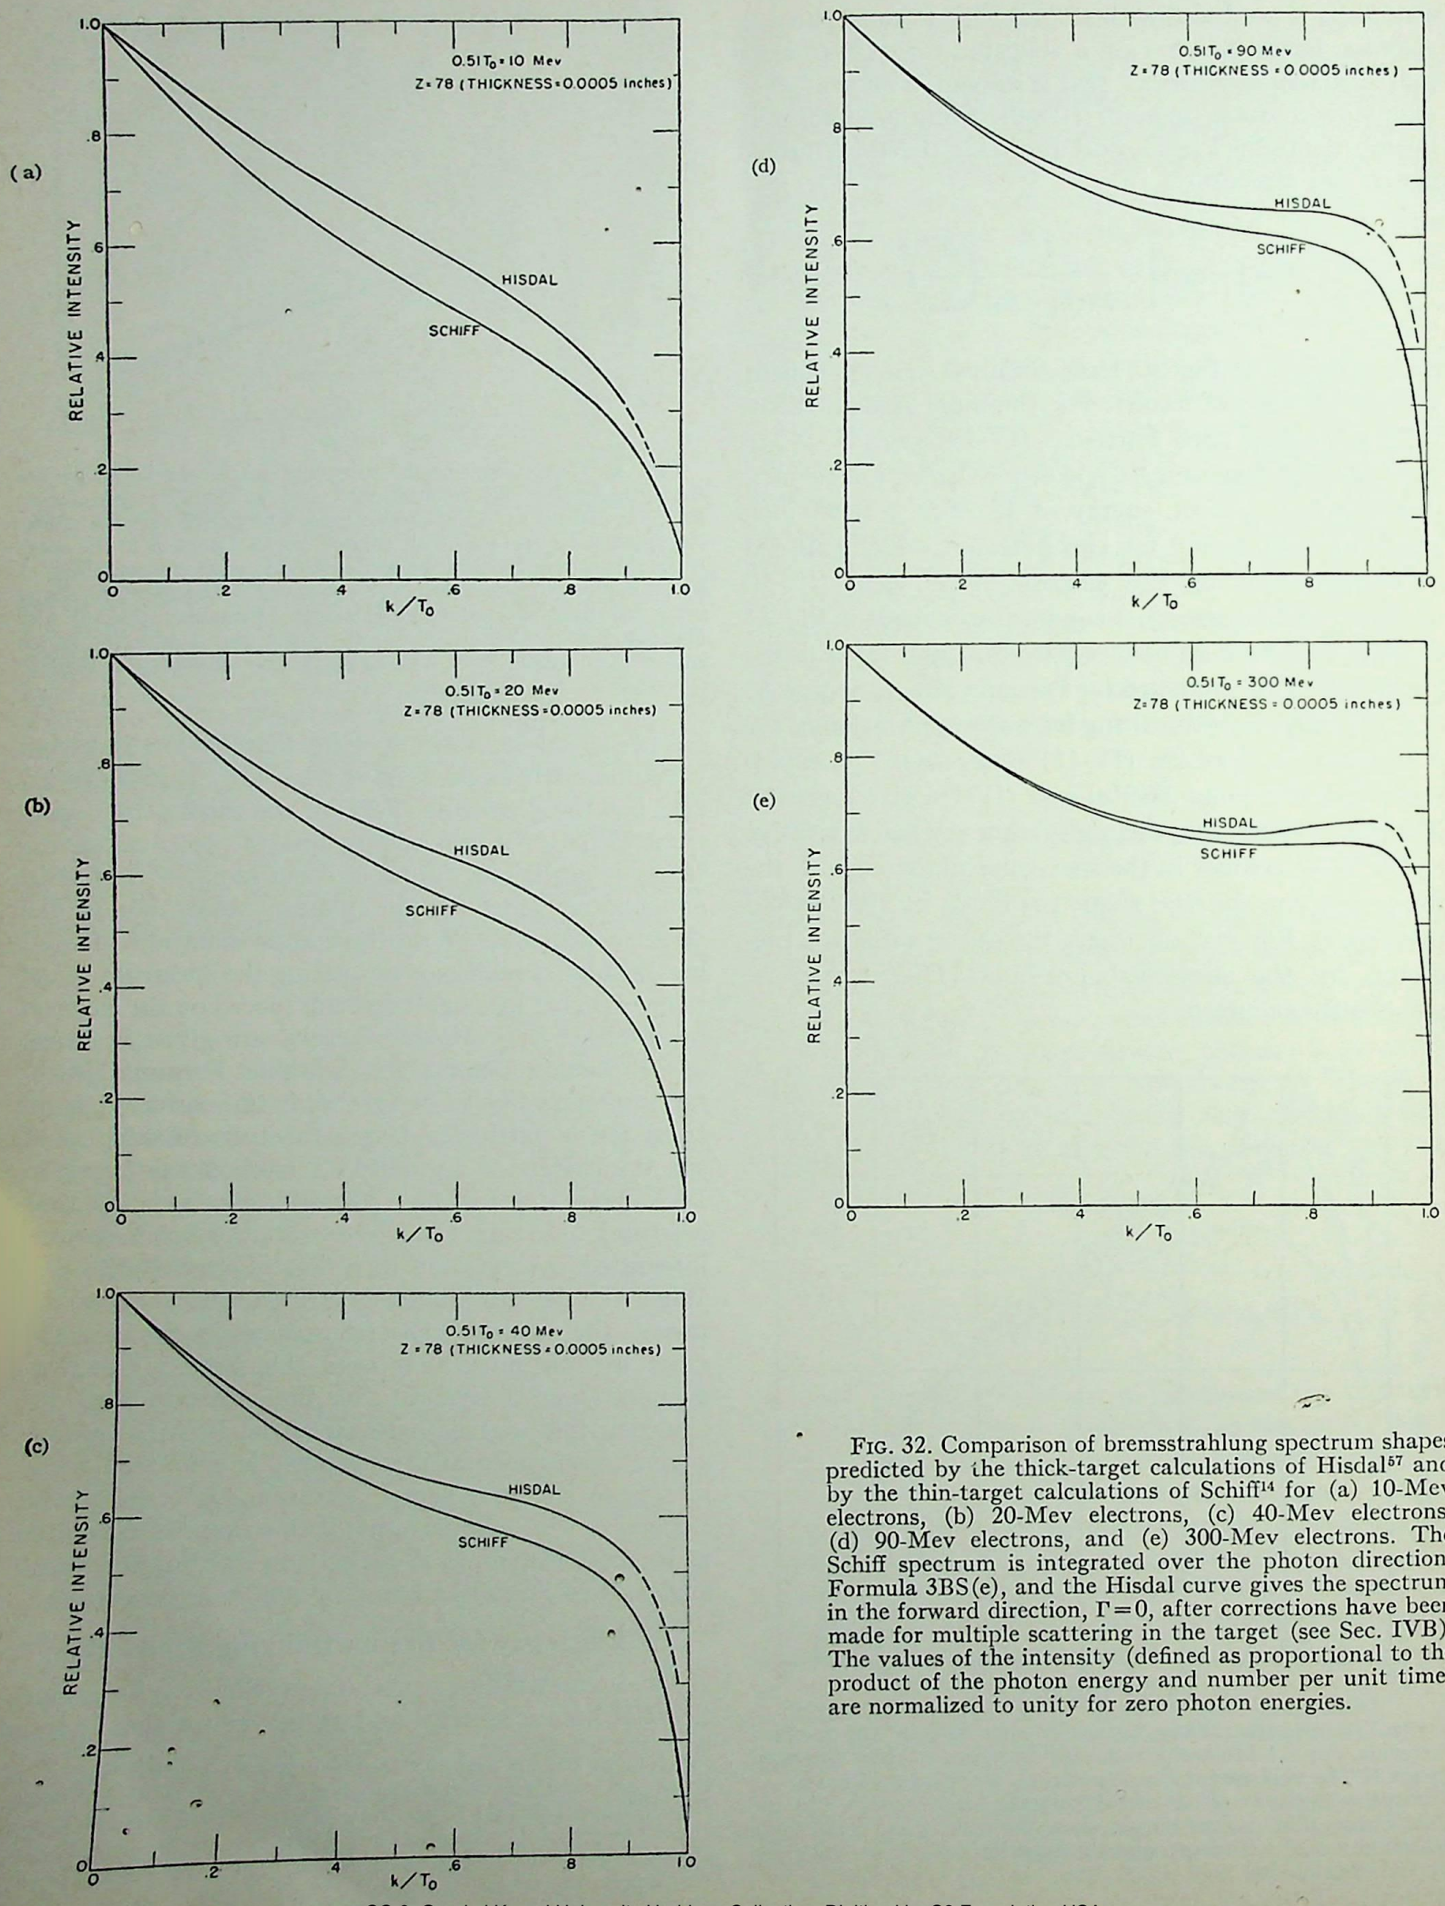

FIG. 32. Comparison of bremsstrahlung spectrum shapes predicted by the thick-target calculations of Hisdal[67] and by the thin-target calculations of Schiff[14] for (a) 10-Mev electrons, (b) 20-Mev electrons, (c) 40-Mev electrons, (d) 90-Mev electrons, and (e) 300-Mev electrons. The Schiff spectrum is integrated over the photon direction, Formula 3BS(e), and the Hisdal curve gives the spectrum in the forward direction, $\Gamma=0$, after corrections have been made for multiple scattering in the target (see Sec. IVB). The values of the intensity (defined as proportional to the product of the photon energy and number per unit time) are normalized to unity for zero photon energies.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

as the ratio of the total bremsstrahlung power radiated when an electron current is incident on a target to the total power in the incident electron beam. The results of various theoretical and experimental determinations of the efficiency are given in the following.

(1) *Nonrelativistic and Intermediate Energies*

The efficiency results for this energy region apply only to the cases in which the electrons expend all of their kinetic energy in the target. Experimental determinations are complicated by (a) the large photon absorption in the target and (b) the large electron backscattering from the target.[49] In the available measurements of the efficiency, corrections have been made for effect (a) but not for effect (b). Therefore, these experimental efficiencies are less than the values that would be obtained if all of the electrons were completely stopped in the target.

In this low-energy region, most experimental and theoretical results[58] are in agreement within a factor of two with an efficiency, ϵ, given by the following formula:

$$\epsilon = 5\times 10^{-4} Z \mathcal{T}_0. \qquad \text{(IV-16)}$$

(2) *Relativistic Energies*

(*a*) *Intermediate thickness targets.*—A target is defined to have an intermediate thickness if the incident electrons do not expend all of their energy as they traverse the target. This condition usually exists in high-energy electron accelerators.

The efficiency of bremsstrahlung production for targets having an intermediate or small ($\ll t_0$) thickness can be estimated from the expression

$$\epsilon = [(d\mathcal{E}_0)_R/\mathcal{T}_0] \sim Kt, \qquad \text{(IV-17)}$$

where $(d\mathcal{E}_0)_R$ is the energy loss by radiation, t is the target thickness in units of the radiation length t_0 [Formula (IV-2)] and K is the radiation probability correction factor given in Fig. 25.

(*b*) *Thick targets.*—For thick targets, the incident electrons lose all of their energy in the target. Formula (IV-16) obviously does not apply at high energies for which the efficiency must remain less than one. An approximate relation for the efficiency in this high energy region has been derived[59] by assuming that the total electron energy loss per unit path length can be written as

$$-\frac{d\mathcal{E}_0}{dx} = -\left(\frac{\rho Z}{A}\right)\{6+3.5\times 10^{-3}\mathcal{E}_0 Z\}, \qquad \text{(IV-18)}$$

where ρ is the density and A the atomic weight of the target material, and where the first term is the collision loss and the second term is the radiation loss. Integration from the initial energy $\mathcal{E}_0$ to 1 gives the following distance, x_0, traveled by an electron in losing all of its energy:

$$x_0 = \frac{A}{3.6\times 10^{-3}\rho Z^2}\ln(1+6\times 10^{-4} Z\mathcal{E}_0). \qquad \text{(IV-19)}$$

Then the efficiency becomes

$$\epsilon = 1-\frac{\text{collision loss}}{\mathcal{E}_0} = 1-\frac{6\rho Z}{A}\frac{x_0}{\mathcal{E}_0} = \frac{3\times 10^{-4} Z\mathcal{T}_0}{1+3\times 10^{-4} Z\mathcal{T}_0}. \qquad \text{(IV-20)}$$

This procedure does not account for the large fluctuations in the radiation loss process and, therefore, provides only a rough estimate of the efficiency. At low energies, Formula (IV-20) reduces to $3\times 10^{-4} Z\mathcal{T}_0$, which agrees roughly with Formula (IV-16). Some representative values of the efficiency obtained from Formula (IV-20) are given in Table VII. These values do not include corrections for the x-ray absorption in the target, which cannot be neglected for most situations.

TABLE VII. Approximate percentage efficiencies for x-ray production.

$\mathcal{T}_0$:	2	4	10	20	50	600
Carbon	0.36	0.72	1.77	3.47	8.3	52

1. INTRODUCTION

CONSIDER an electron trap in a solid with two levels, u (upper) and g (ground). A fundamental question is: how does an electron transition affect the normal vibrational modes of the crystal? The answer so far has been obtained either with the use of a phenomenological macroscopic theory, or by the use of configurational coordinate curves.

The phenomenological theory, due to Fröhlich (F1,* F2, and H4; also Born and Huang, B2, p. 82), ignores details of the lattice structure. In a polar crystal Fröhlich assumes that the forces on the ions, as well as the polarization, depend exclusively on the macroscopic electric field and relative ionic displacements at the point in question. This model leads to pure transverse and longitudinal modes. It is only true for the longest "optical" waves in which the positive and negative ions vibrate 180° out of phase. This theory does not account for the change in the character of the normal mode with decreasing wavelength. In NaCl the longitudinal optical branch in certain directions has a frequency drop of 57%, and the shortest waves are pure acoustical, in which the ions vibrate in phase (M3). Fröhlich's model is useful in the theory of reststrahlen where one deals with electromagnetic radiations whose wavelength is large compared to the inter-ionic distances, but this approach is questionable for phenomena which depend critically on short range effects.

The configurational coordinate model assumes that a very small number of local modes surround a point imperfection. This approach is supported by recent calculations. (See M2 and references therein.) One would expect the local modes to have frequencies in the gap between the acoustical and optical branches. This suggests that their frequency spread may be small. We refer to this model by the letters LM. It is assumed that there are one or several "effective" frequencies associated with the local modes. The extreme situation where there is only one mode is referred to by the letters CC (configuration coordinate, D1). The LM models cannot give a completely correct picture since long range effects must exist in polar solids. The Fröhlich model cannot either, since it ignores local lattice distortions.

One of the most important effects of the electron-phonon interaction is the broadening of optical absorption lines. Studies of these phenomena will give information regarding the effects of electronic transitions on normal modes.

In general, rigorous quantum mechanics has been used on this problem when the phenomenological model is employed. The original techniques required infinitely small interaction between the trapped electron and the modes. It, therefore, could not be used in the LM or CC models.

While these developments were taking place, Williams (W2), as well as Williams and Hebb (W3), developed

* Refer to items in the Bibliography at the end of the paper.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

an independent treatment which was applied to the CC model. This approach makes a series of approximations and is sometimes referred to as "semiclassical." A more detailed justification of Williams' method has been made by Lax (L1), Klick (K2), and Dexter (D1). This development shows that at very low temperatures the shape of an absorption band should be Gaussian (provided that the electronic transition does not induce a frequency change in the CC mode). Further, the position of maximum absorption is temperature independent even if the frequency changes.

Since 1950 the rigorous quantum mechanical method has been fully developed, and one can now apply it to various LM models. Williams' simpler approach is still very useful, since it gives a vivid picture of the absorption process. However, it is beset by many approximations, and the final results do not always agree with more rigorous calculations.

To summarize the development so far, we have several models—phenomenological (Fröhlich), local modes, and configurational coordinate. We have two means of calculating shapes of bands—Williams', and the rigorous quantum mechanical approach. For some models the second method can be carried through in detail. Most realistic ones, however, require Williams' approach. A rather formal theory for all models has been worked out by Kubo and Toyozawa (K6).

This paper attempts to synthesize the rigorous theory and to apply it to various models. We start by examining the Hamiltonian to be used (Part I). Fortunately, it can be written in a form that applies to all the models. We next discuss the properties of these Hamiltonians and point out the essential difference between phonon-electron and photon-electron interactions. Only in special types of solid state problems may they be considered similar. At this stage, one can see why multiphonon processes occur. Some of the results of Part I are known, but their interrelations have not been fully understood. This has led to appreciable confusion. Some of the mathematical techniques are those used by Born and Huang in connection with another problem.

After this development, the photon absorption problem is considered rigorously and in some detail (Part II). The Hamiltonian developed permits a unification of the field which is most desirable, since experimental results are being obtained.

Applications of the theory are not considered because the author does not trust the presently available data. The absorption band associated with the F center in KCl has been measured a great many times. It seems to fulfill the requirement stated in the first paragraph. Various laboratories, however, do not report the same results. A typical set of half-width, H, measurements are shown in Table I.†

At low temperatures H can be measured to about five parts per thousand so that the variations cannot be attributed to experimental error (M1). The author doubts that the scatter is related to the sample purity, and the temperature variation of H is too small to explain the discrepancies. Experiments have shown (K3) that, unless special care is taken, any values between 0.19 ev and 0.25 ev can be obtained for H (in KCl at 78°K). Improper quenching and very slight exposure to light produce new bands, and H then corresponds to a composite.

TABLE I. H of KCl.

θ (°K)	H (ev)	Observer
28	0.19	Mollow (M10)
4	0.18	Russell and Klick (R1)
4	0.17	Burstein and Oberly (B5)
5	0.168	Compton and Klick (C3)

85 (App)	0.26	Molnar (M11)
87	0.23	Mollwo (M10)
87	0.243	Kanzaki (K1)
77	0.3	van Doorn and Haven (D3)
77	0.22	Russell and Klick (R1)
77	0.20	Burstein and Oberly (B5)
78	0.20	Duerig and Markham (D2)
78	0.193	Konitzer and Markham (K4)
77	0.196	Compton (C2)

Although not comparing the results with experiment, an attempt is made to present the argument in such a manner that a comparison with data is readily possible. Indeed, a comparison has been made with recent data on the F center in KCl. The agreement on the whole is satisfactory. It is hoped that in the next few years sufficient experimental data will become available to justify and amplify the theory presented here.

The first theory of the shape of an absorption band in a solid is due to Smakula (S2), who assumed that a trapped electron behaves like a damped oscillator in a dielectric medium. Nothing in this theory explains the temperature dependence of the damping term. The first attempt to associate the width theoretically with the thermal vibration was done independently by Muto (M13), by Huang and Rhys (H5), and by Pekar (P1) (also P2, 3, and 4). Huang-Rhys and Pekar used Fröhlich's model and assumed that the electron interacts only an infinitesimally small amount with all the longitudinal optical modes. Thus they limited themselves to first order terms in the various expansions, as did Muto.

Pekar obtained two expressions for the shape; it should be nonsymmetric at low temperatures but Gaussian at high temperatures. He employed the reststrahlen frequency combined with the Lyddane-Sachs-Teller (LST) relation to determine the longitudinal frequency (B2, p. 82–128). He also made a comparison of his theory with Mollwo's data (M10).

O'Rourke (O1) made a fundamental extension of the previous calculations, eliminating the restriction that

† Half-width is defined in Appendix I.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

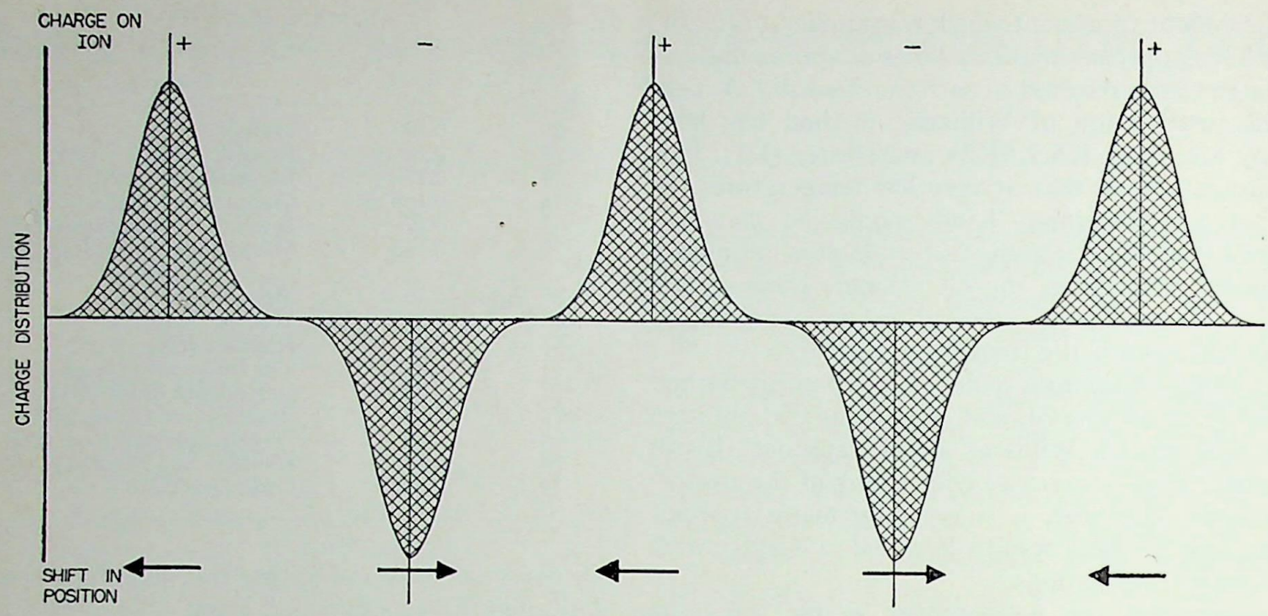

FIG. 1. Schematic diagram showing the effects of trapping an electron at an imperfection.

the electron-phonon interaction must be infinitely small. His most general expressions are limited by the assumption that electronic transitions do not cause frequency changes. To use his expressions one must assume that a single "effective" vibrational frequency exists. His results apply to the Fröhlich Hamiltonian, the CC model, as well as to an LM model, if a single effective frequency exists. Pekar's expansions may therefore be combined with the CC or LM model to calculate the shape rigorously at very low temperatures. We do this and show that the shape is not the one predicted on the basis of the Williams' approximation. Present low-temperature data indicate that the more rigorous treatment is correct.

At about the same time, Lax (L2) developed some completely general relations between the moment of the distribution and the temperature. Meyer (M8 and 9) extended the development of Lax, giving a general approach to the problem. This method is not limited to Fröhlich's Hamiltonian which was employed by Meyer. For the calculation to be valid, it is necessary to use an orthogonal set of eigenfunctions. We show here that this is true. Further, we indicate that Meyer omits some important terms.

Meyer also made a serious attempt to analyze Mollwo's data by means of the new theories. His results are most impressive and by themselves give a good proof of the reliability of his calculation and a validity of the LST relation. This is not confirmed by more recent measurements (see Table I). The method of analysis to be employed is of fundamental importance. An alternate analysis of Mollwo's data indicates that the effective frequency is 3.2×10^{12} sec^{-1} for KCl. The LST relation gives 6.3×10^{12} sec^{-1}. This difference suggests that Fröhlich's model does not apply to the F center in KCl. Other analyses (R1, K4) support this view. The means of analysis is the important difference between Meyer's conclusion and those obtained recently.

This field has been reviewed by Pekar (P3, P4), Lax (L2), Meyer (M9), Klick and Schulman (K2a), and Dexter (D1). Pekar's reviews, though out of date, are extremely important contributions to the field. Lax's review concerns itself primarily, though not entirely, with Williams' approximation. Meyer's review is limited to Fröhlich's model and omits some important developments made by Pekar. Klick and Schulman consider only Williams' approach. Dexter considered both aspects of the problem, applying the quantum mechanical treatment to Fröhlich's model and Williams' approximation to the CC model.

This paper concentrates on the pure quantum mechanical approach and treats all models. Some aspects of the problem are considered in greater detail than has been done previously. These aspects are most important since they can be checked experimentally.

The theory is not developed in full; instead, results are quoted from the recent book of Born and Huang (B2), which is cited by the letter B. Those parts of the theory which have not been presented in book or review article form are more fully discussed. Although the theory applies to any imperfection with two or more bound states, the development is closely related to the F center, since this has been studied in greatest detail.

Part I. The Hamiltonian

2. PHYSICAL CONCEPTS INVOLVED IN ELECTRON-PHONON INTERACTIONS

The trapping of an electron at a site has three effects. These can be intuitively understood by means of Fig. 1, which is a schematic representation of the nuclei

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

(shielded by the inner electrons) for a one-dimensional polar crystal.

The nuclei of the solid are assumed to be initially distributed uniformly. When an electron is trapped nearby (to the left of the diagram) the following effects occur.

(1) The electron induces a force on the nuclei, causing a nonuniform shift of the rest positions, as indicated by the arrows. This action is very much like a compression (or expansion) of a spring and leads to the storing of energy.

(2) The forces between the nuclei are slightly modified, leading to a shift in the angular frequencies of the lattice, $\Delta\omega$. At absolute zero the probable position of an ion is given by a Gaussian curve if an Einsteinian model is used (no coupling between ions). The trapping causes a broadening or narrowing of the distribution. The Einsteinian solid is used here only to illustrate the effect.

(3) Finally, there is a third effect similar to a photon-electron interaction—the electron's self-energy. The electrons and nuclei readjust their probable distributions so that the total energy is at a minimum. This effect may be visualized by means of time dependent perturbation theory leading to electron-phonon transitions, or by time independent perturbation theory (or even variational methods) leading to wave functions which are no longer single products of electronic and nuclear wave functions. This is referred to as the electron-nuclear correlation.

These effects also occur when an electron redistributes itself, i.e., acquires a new wave function by jumping from one bound state to another, or by transitions to the conduction band. Item (3) is similar to phenomena which occur in electrodynamics, while (1) and (2) arise in systems made of light and heavy particles. The relative importance of these effects depends on the forces within the solid. In many solids, effects (1) and (2) are so small that phonon-electron interaction problems resemble problems in electrodynamics. This is true in metals and in some semiconductors. In general, the phonon-electron problem has a different character because of effects (1) and (2). Our interest here is the difference between phonon-electron and photon-electron interactions; hence, effect (3) is not considered in detail. Usually the effects are considered independently.

Treatments of the correlation problem appear several places and take various forms. Born and Huang (B, p. 166) considered it briefly in a general manner, while Haken (H1) studied its effect in a special one-dimensional model.

Simpson (S3) and Pekar (P3) considered effect (1) in their calculations on the F center. Williams (W2) in an ambitious and detailed study calculated the displacements which occur when a Tl^+ ion replaces a K^+ ion in a KCl lattice. Williams finds a change in the second derivative of his CC plots which is related to $\Delta\omega$. Klick and Schulman (K2a) have attempted to compute $\Delta\omega$ from experimental data.

The idea of a large frequency shift was invoked by Seitz (S1) to explain the observations of Dutton and Maurer (D4). They measured a thermal activation energy for the V_1 band in KBr of 0.23 ev compared to an optical activation energy of 3.0 ev. These ideas have some theoretical difficulties. A similar problem exists for the F' center whose optical activation energy in KBr is 1.3 ev compared to a thermal activation energy of 0.29 ev (D4).

A problem which involves all three effects is an electron at the bottom of the conduction band in a polar solid. The electron interacts strongly with the surrounding ions. Due to the large difference in the velocity of the electrons and the nuclei, the forces on the nuclei depend on the average distribution of the electron, thus the electron displaces the surrounding ions. This causes effects (1) and (2) and results in a potential well. The well in turn traps the electron. The electron will also be influenced by the polar modes of vibration about the well. This is similar to the interaction between an electron and the zero-point electromagnetic vibrations. The presence of the well may be referred to as self-trapping,‡ while the electron-phonon interaction may be called the polaron effect. In reality, they cannot be separated, although at present the connection between the two is not completely clear.

3. FORMAL THEORY

The complete Hamiltonian for a solid of unit volume is

$$H=T_e+T+V(\mathbf{R}). \tag{3.1}$$

Here T_e is the kinetic energy operator for all the electrons, T is the kinetic energy operator for the N nuclei, and V is the total potential energy of the system. V depends on the position of all the electrons (denoted by $\mathbf{r}$ when explicitly stated) and all the nuclei (denoted by $\mathbf{R}$). We include in V implicitly any point imperfection such as a missing ion. The notation of (B) will be used, namely, the coordinate of a nucleus is $X_\alpha(k)$ ($\alpha=1, 2, 3$ and $k=1, 2\cdots N$). The explicit expression for T is

$$T=-(\hbar^2/2)\sum_k (1/M_k)\nabla_k^2, \tag{3.2}$$

where all the nuclei need not have the same mass, M_k.

The Born-Oppenheimer technique assumes that for a fixed value of $\mathbf{R}$ the eigenfunctions, $\varphi_n(\mathbf{R})$, and eigenvalues, $\epsilon_n(\mathbf{R})$, associated with the operator

$$h_e(\mathbf{R})=T_e+V(\mathbf{R}) \tag{3.3}$$

are known.

‡ The assumption has been made that the self-trapping concept implies a stationary distortion of the lattice. There is no reason for this assumption. Indeed, Seitz and the author (M6) suggested at an early date that a self-trapped electron might move through the lattice. The work of Castner and Kanzig (C1) implies that a self-trapped hole has relatively little mobility.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Next, one uses the Hamiltonian

$$h_v(\mathbf{R}_n)=T+\epsilon_n(\mathbf{R})-\epsilon_n(\mathbf{R}_n) \tag{3.4}$$

to obtain a second set of eigenfunctions χ and eigenvalues ϵ_v. The point $\mathbf{R}_n$ of (3.4) is defined by the relations

$$[\partial\epsilon_n/\partial X_\alpha(k)]_{\mathbf{R}_n}=0. \tag{3.4a}$$

To terms in $[\Delta X_\alpha(k)]^3$ we may write (3.4) in the form

$$h_v=T+\tfrac{1}{2}\sum_{\alpha,\beta,k,l}\left[\frac{\partial^2\epsilon_n}{\partial X_\alpha(k)\partial X_\beta(l)}\right]_{\mathbf{R}_n}\Delta X_\alpha(k)\Delta X_\beta(l). \tag{3.5}$$

Here $\Delta X_\alpha(k)$ is the displacement relative to $\mathbf{R}_n$. One may introduce normal coordinates into (3.5) (B, p. 173) which are linear functions of the $\Delta X_\alpha(k)$. The result is

$$h_v=\tfrac{1}{2}\sum_j(p_j^2+\omega_j^2q_j^2), \tag{3.6}$$

where

$$p_j=(\hbar/i)(\partial/\partial q_j), \tag{3.6a}$$

and j goes from 1 to 3 N. The q's have the dimension of length times (mass)$^{\frac{1}{2}}$ and the ω's are given by the secular determinant,

$$\left|\frac{1}{(M_kM_l)^{\frac{1}{2}}}\left[\frac{\partial^2\epsilon_n}{\partial X_\alpha(k)\partial X_\beta(l)}\right]_{\mathbf{R}_n}-\omega^2\delta_{\alpha\beta}\delta_{kl}\right|=0. \tag{3.7}$$

Here δ is the Kronecker delta.

The individual term in (3.6) corresponds to a simple harmonic oscillator with an eigenfunction, χ_{nj}, and an eigenvalue, $\hbar\omega_j(v_j+\frac{1}{2})$. The eigenfunctions associated with h_v are products of such functions and are denoted by χ_n. n corresponds to an electronic state and appears through the use of $\epsilon_n(\mathbf{R})$, and v_j is the vibrational quantum number of the jth mode. v_t is the sum of the v_j's. Since we are mainly concerned with two states, n will at times be replaced by g (ground) and u (upper). Usually the subscript n will not be required. φ and χ will be used for the ground state while φ' and χ' will be employed for the excited state.

To complete the notation, the following definitions are made:

$$\langle\varphi_{n'}|\mathbf{O}|\varphi_n\rangle=\int\varphi_{n'}{}^*\mathbf{O}\varphi_n d\tau, \tag{3.8}$$

where the integration is over all positions of the electrons, and

$$\{\chi_{n'}|\mathbf{O}|\chi_n\}=\int\chi_{n'v'}{}^*\mathbf{O}\chi_{nv}d\mathbf{R}, \tag{3.9}$$

where the integration is over all positions of the nuclei. $\mathbf{O}$ is any operator. It will be omitted when $\mathbf{O}=1$.

The essential problem is to find approximate eigenfunctions for the total Hamiltonian (3.1). By using the foregoing equations, we may define two approximations:

(1) the static—$\Psi(S)=\varphi(\mathbf{R}_n)\chi$ (3.10)

or

(2) the adiabatic—$\Psi(A)=\varphi(\mathbf{R})\chi$. (3.11)

Neither (3.10) nor (3.11) is a complete solution of (3.1). For some problems one desires to split H into a zeroth-order Hamiltonian and a residual which represents a small perturbation. The way this is done depends on the form of Ψ employed.

For the static approximation

$$H_0(S)=h_e(\mathbf{R}_n)+h_v(\mathbf{R}_n) \tag{3.12a}$$

$$H_1(S)=V(\mathbf{R})-V(\mathbf{R}_n)$$

$$-\tfrac{1}{2}\sum_{\alpha,\beta,k,l}\left[\frac{\partial^2\epsilon_n}{\partial X_\alpha(k)\partial X_\beta(l)}\right]_{\mathbf{R}_n}\Delta X_\alpha(k)\Delta X_\beta(l). \tag{3.12b}$$

On the other hand, in the adiabatic approximation,

$$H_0(A)\varphi(\mathbf{R})\chi=\chi h_e(\mathbf{R})\varphi(\mathbf{R})+\varphi(\mathbf{R})T\chi \tag{3.13a}$$

$$H_1(A)\varphi(\mathbf{R})\chi$$

$$=-\frac{\hbar^2}{2}\sum_k\left[\frac{2}{M_k}\nabla_k\varphi\cdot\nabla_k\chi+\frac{1}{M_k}\chi\nabla_k{}^2\varphi(\mathbf{R})\right]. \tag{3.13b}$$

$H_0(A)$ assumes that $\varphi(\mathbf{R})$ permutes with T.

An elegant method of arriving at (3.12) was given many years ago by Born and Oppenheimer (B3). This treatment is reproduced in a simpler form by (B, pp. 166–173), who have also found a systematic way to obtain the adiabatic approximation. In the latter case, the χ's contain higher-order anharmonic terms. The Born-Oppenheimer technique involves several steps. Equation (3.4a) is a particularly important one, since it is involved in h_v. Limitations on this technique are discussed in Sec. 5(b).

To obtain the eigenvalues of (3.13a) we may proceed as follows:

$$\begin{aligned}H_0(A)\varphi(\mathbf{R})\chi&=\varphi(\mathbf{R})[\epsilon_n(\mathbf{R})+T]\chi\\&=\varphi(\mathbf{R})[\epsilon_n(\mathbf{R}_n)+h_v]\chi\\&=[\epsilon_n(\mathbf{R}_n)+\epsilon_v]\varphi(\mathbf{R})\chi,\end{aligned} \tag{3.14a}$$

where (3.4a) and (3.5) have been used. The eigenvalues $H_0(S)$ and $H_0(A)$ are equal since

$$H_0(S)\varphi(\mathbf{R}_n)\chi=[\epsilon_n(\mathbf{R}_n)+\epsilon_v]\varphi(\mathbf{R}_n)\chi. \tag{3.14b}$$

In view of (3.14a) and (3.14b) we define the total energy of the system as $E_{nv}=\epsilon_n(\mathbf{R}_n)+\epsilon_v$. We shall again omit the subscripts, using E and E'.

The method of splitting H into parts is based on a physical intuition and the fact that the nuclear mass is much heavier than the electron mass. Mathematically, the splitting has an unfortunate aspect, since some of the nicest mathematical properties do not hold for the H_0's.

One may show (M4) that (1) the static eigenfunctions do not form an orthogonal complete set while (2) the adiabatic eigenfunctions form an orthogonal set with respect to $\mathbf{r}$ and $\mathbf{R}$ space.

The latter can be shown by noting that the $\varphi(\mathbf{R})$'s form a complete set of functions in $\mathbf{r}$ space for a fixed $\mathbf{R}$,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and that the χ's form a complete set in $\mathbf{R}$ space for a fixed n. Further, we note

$$\{\langle\varphi_{n'}(\mathbf{R})\chi_{n'v'}|\,\varphi_n(\mathbf{R})\chi_{nv}\rangle\}=\{\chi_{n'v'}\langle\varphi_{n'}(\mathbf{R})|\,\varphi_n(\mathbf{R})\rangle\chi_{nv}\}$$
$$=\{\chi_{n'v'}|\,\delta_{nn'}|\chi_{nv}\}=\delta_{nn'}\delta_{vv'}. \quad (3.15)$$

(3) It can be shown that (B, p. 189)

$$\left[\frac{\partial\epsilon_n}{\partial X_\alpha(k)}\right]_{\mathbf{R}_n}=\left\langle\varphi_n(\mathbf{R}_n)\left|\left[\frac{\partial V}{\partial X_\alpha(k)}\right]_{\mathbf{R}_n}\right|\varphi_n(\mathbf{R}_n)\right\rangle \quad (3.16)$$

(Feynman's Theorem).

For a perfect ionic crystal the lowest eigenvalue of h_e is the total interionic potential, i.e., the coulombic, repulsive, and high-order terms, from which one determines the normal modes by well-developed methods. In the case of interest, all cells in our solid are not equivalent, since there is a point imperfection. In the case of the F center there is a missing negative ion with a trapped electron. Mazur, Montroll, and Potts (M2) have shown that the modes for such a crystal are not identical to those of a perfect lattice. A missing ion creates local modes surrounding the imperfection. These are the vibrations of greatest interest to our problem. In a general way the motion of the ion right around an imperfection is determined primarily by the local modes (Bjork, B1). The object here is not to describe these modes in detail but to indicate what effects electron transitions have on them. The exact relation between local and crystal modes is an extremely complex problem. One of the best ways to study the local modes is to measure their frequencies indirectly. This can be done from measurements of the thermal broadening of absorption and emission bands (Part II).

(a) Ground State

The development so far is completely general. We now use this development for a crystal with an electron trap. Assume that there are two (or more) bound states. Every state generates its own ϵ_n, ω_j's, and q_j's. We start the calculation by using the values appropriate for the ground state. To stress this point we write ϵ_g for ϵ_n; $\omega_j(g)$ for ω_j; $h_v(g)$ for h_v, etc. We shall retain the notation q_j and p_j, however.

(b) Upper State

We could make all the equations apply to the upper state by simply replacing the subscript g by u. The p's and q's of (3.6), however, will be different. The object is to find relations between the two sets; hence, we proceed in a different manner. In this case, the eigenvalue of h_e is $\epsilon_u(\mathbf{R})$ and the trapping energy may be defined as

$$\Delta\epsilon(\mathbf{R})=\epsilon_u(\mathbf{R})-\epsilon_g(\mathbf{R}). \quad (3.17)$$

$\Delta\epsilon$ is approximately equal to the energy the trapped electron acquires when it is excited from one state to another (the nuclear coordinates remain at $\mathbf{R}$). Actually, the difference in energy is related to all the electrons rather than just one.

Since we are interested in the q's, $\epsilon_u(\mathbf{R})$ is expressed as

$$\epsilon_u(\mathbf{R})=\epsilon_g(\mathbf{R})+\Delta\epsilon(\mathbf{R})=\epsilon_g(\mathbf{R}_g)+\tfrac{1}{2}\textstyle\sum_j\omega_j^2(g)q_j^2$$
$$+\Delta\epsilon(\mathbf{R}_g)+\textstyle\sum_j\epsilon_jq_j+\tfrac{1}{2}\sum_{jk}\epsilon_{jk}q_jq_k+\cdots, \quad (3.18)$$

where

$$\epsilon_j=[\partial\Delta\epsilon/\partial q_j]_{\mathbf{R}_g} \quad (3.18a)$$

and

$$\epsilon_{jk}=[\partial^2\Delta\epsilon/\partial q_j\partial q_k]_{\mathbf{R}_g}. \quad (3.18b)$$

The dimension of ϵ_j is (mass)$^{\frac{1}{2}}$ (length) (time)$^{-2}$ while the dimension of ϵ_{jk} is simply (time)$^{-2}$. The second term in (3.18) arises because $\epsilon_g(\mathbf{R})-\epsilon_g(\mathbf{R}_g)=\frac{1}{2}\sum_j\omega_j^2(g)q_j^2$, which follows from the definition of the q's.

At this point the theory runs into some difficulties. Equation (3.4) assumes that terms in $\Delta X_\alpha(j)\Delta X_\beta(k)\times\Delta X_\gamma(l)$ are so small that they can be neglected. If the q's are determined by thermal vibrations, they will be small at low temperatures. Equation (3.18) includes, however, the displacement which occurs during a transition, i.e., the difference between $\mathbf{R}_u$ and $\mathbf{R}_g$ defined by

$$[\partial\epsilon_g/\partial R]_{\mathbf{R}_g}=0 \quad (3.19a)$$

and

$$[\partial\epsilon_u/\partial R]_{\mathbf{R}_u}=0. \quad (3.19b)$$

Actual calculations of the difference between the $\mathbf{R}$'s have been made on some simple models. $\mathbf{R}_g-\mathbf{R}_u$ is about 0.3 A for the nearest neighbor in the case of a Tl^+ trap in KCl (W2) and 0.06 A for the self-trapped electron (M6). These results are to be compared to the root-mean-square displacement of an atom (Einsteinian model with a mass equal to 30 times that of the proton and frequency of 5×10^{12}). For $n=0$ (the quantum vibrational number), it is 0.06 A and increases to 0.13 A for $n=2$. X-ray measurements of the root-mean-square amplitude of vibration in NaCl at 86°K gives 0.15 A for Na^+ and 0.13 A for Cl^- (L3, p. 50). These large values must be attributed to the lower-frequency modes. The self-trapping calculations showed that the first anharmonic term was of no importance, due to a fortuitous geometry. However, this is not a general conclusion. If we include additional terms in (3.18), there seems to be no apparent simple way to relate the normal modes in the upper and lower states. Therefore, we consider (3.18) to be exact. For shallow traps and for any trap in nonionic crystals, this assumption must be *good*. It must also be a *fair* approximation for deeper traps in ionic crystals, such as the F center.

It is further assumed that the modes are nondegenerate. To those familiar with Fröhlich's phenomenological treatment, this may seem like a radical assumption indeed. One must remember that Fröhlich's approximation is not supported by detailed calculations

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

(M3). Secondly, we may be dealing to a large extent with local modes. This is supported by the analyses on the shape of the absorption bands. These are in the forbidden gap and cluster about a single value. There is no reason, however, to assume that the local modes are actually degenerate, and the above assumption is a natural one at the present stage of development. This assumption probably does not affect any major conclusions of this paper.

Now the transformation

$$q_j = q_j' + \sum_k{}' \frac{\epsilon_{jk}}{\omega_k^2(g) - \omega_j^2(g)} q_k' \tag{3.20}$$

is made. The prime on the sum indicates that $j \neq k$. Neglecting terms of order $\epsilon_{ij}\epsilon_{kl}$ or $\epsilon_j\epsilon_{kl}$ for $(k \neq l)$, (3.20) gives an orthogonal transformation. To the same approximation we write

$$\epsilon_u(\mathbf{R}) = \epsilon_g(\mathbf{R}_g) + \Delta\epsilon(\mathbf{R}_g) + \tfrac{1}{2}\sum_j \omega_j^2(u)(q_j')^2 + \sum_j \epsilon_j q_j' \tag{3.21}$$

$$\omega_j^2(u) = \omega_j^2(g) + \epsilon_{jj}. \tag{3.21a}$$

The new equilibrium position is obtained from (3.19b). Since the ΔX's are linear functions of the q's, (3.19b) gives

$$(\partial/\partial q_j')\epsilon_u = \omega_j^2(u) q_j' + \epsilon_j = 0. \tag{3.22}$$

The shift in the equilibrium position is

$$q_j' = -\epsilon_j/\omega_j^2(u). \tag{3.23}$$

Thus, the final transformation

$$Q_j = q_j' + \epsilon_j/\omega_j^2(u) = q_j' - \Delta q_j \tag{3.24}$$

gives the energy of the ground state in the form

$$\epsilon_u(\mathbf{R}) = \epsilon_g(\mathbf{R}_g) + \Delta\epsilon(\mathbf{R}_g) - \tfrac{1}{2}\sum_j \epsilon_j^2/\omega_j^2(u) + \tfrac{1}{2}\sum_j \omega_j^2(u) Q_j^2 \tag{3.25}$$

$$= \epsilon_u(\mathbf{R}_u) + \tfrac{1}{2}\sum_j \omega_j^2(u) Q_j^2. \tag{3.25a}$$

By direct substitution one may show that

$$\sum_j \left(\frac{\partial}{\partial q_j}\right)^2 = \sum_j \left(\frac{\partial}{\partial q_j'}\right)^2 = \sum_j \left(\frac{\partial}{\partial Q_j}\right)^2, \tag{3.26}$$

hence, the transformation does not modify T.

The first three terms on the right of (3.25) appear in the eigenvalue of h_e. The derivation serves to show the relation between the q's and Q's. This is of essential importance and not the final form of ϵ_u.

This concludes the formal treatment. The assumptions which have been made are now summarized to emphasize their limitations. These are that

(3.27)

(1) all cubic terms can be neglected;

(2) terms in $\epsilon_{ij}\epsilon_{kl}$ and $\epsilon_j\epsilon_{kl}$ for $k \neq l$ can be neglected;

(3) the normal modes are nondegenerate.

In view of the work of Montroll and co-workers, we know that lattice perturbation can localize some of the modes. This effect does not appear above. The transformation (3.20) without the neglect of higher-order terms (item 2) may cause a radical change in the modes. This change most probably does not occur however during an electronic transition.

The third assumption probably is not a fundamental one, although the first two may be. The problem of degenerate modes is that the q's and p's of Eq. (3.6) are not unique. Consider two degenerate modes q_1 and q_2. The substitution $q_1'' = q_1 + q_2$ and $q_2'' = q_1 - q_2$ will not change the required form of the Hamiltonian, and the q'' modes are equally satisfactory. The additional terms which occur in the upper state put a requirement on the possible linear combination of the q's. These can be obtained from argument similar to those used in degenerate quantum mechanical perturbation theory. If we use the proper definition of the q's, the degenerate problem is similar to the nondegenerate one. For this reason, the author feels that item 3 is not an essential restriction. The author has not carried through the details of this argument. Certainly the transformations (3.20) and (3.24) allow one to make a simple synthesis of many theoretical ideas at a time when it is most needed from the experimental point of view. Hence, we assume their validity without any further ado.

For a point imperfection we may expect two types of ϵ_j. The ϵ_j's for the local modes will be especially large in solids with some polar characteristics. This leads to the LM approximation. The ϵ_j's for individual longitudinal modes are very small; the net effect, however, may be large. This leads to Hamiltonians similar to those employed by Fröhlich. For these modes the ϵ_{jj}'s must be extremely small and the transformation (3.20) need not be used.

Item 1 of Sec. 2 enters into the problem through (3.19b) or (3.24), item 2 through $\omega_j(g)$ or (3.21a), while item 3 arises through (3.12b) or (3.13b) depending on the form of Ψ employed.

The technique used on the F center by Huang and Rhys and by Pekar assumes that ϵ_j is of the order of $1/N$. This does not hold for local modes; hence the expansion techniques are questionable. O'Rourke does not require that $\epsilon_j \to 0$, in the first part of his paper, thus includes localized modes.

The division made above regarding the types of modes is not completely satisfactory since the Fröhlich description is somewhat oversimplified. The usual classification of modes, i.e., acoustical *versus* optical, transverse *versus* longitudinal, apply only to the long modes in polar crystals (M3). The majority of the modes actually have a wavelength of the order of several interionic distances and do not fit into the above classification. The experimentalist should remember that the LST relation is not completely reliable, and, therefore, should not take it too seriously. The theorist should attempt to formulate his equations in such a

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

manner that he does not rely on the extreme simplification involved in this relation. As our understanding of the problems treated here increases (this involves further experimental data), we shall undoubtedly obtain much more reliable information regarding the vibrational modes in solids.

4. PHYSICAL INTERPRETATION OF OPTICAL AND THERMAL TRANSFORMATIONS

A physical interpretation of Sec. 3 is now attempted. It starts with a one-dimensional Franck-Condon diagram which will subsequently be elaborated. Next, the various activation energies are defined and their interrelations discussed. The results are applied to the V_1 center.

We start by considering the following simple model: The temperature is 0°K. Only one mode is affected by the transition. This implies that only one ϵ_j is different from zero. In Fig. 2 we plot ϵ_u and ϵ_g as a function of a coordinate q_j. It is convenient, for now, to set $\epsilon_{jj}=0$; hence $\omega_j(u)=\omega_j(g)$. Although ϵ is an eigenfunction of h_e, it is useful to divide it into two parts, namely, $\epsilon_g(\mathbf{R}_0)=\epsilon_g(0)$, which is considered as an electronic energy of the ground state, and $\epsilon_g(q_j)-\epsilon_g(0)$, which is considered as a lattice potential energy. This division is justified by Eqs. (3.14a and b). According to the simplified Franck-Condon principle, the system may absorb a photon and jump from point a to point b on ϵ_u. The use of the Born-Oppenheimer technique assumes that the electron has sufficient kinetic energy to occupy all the space required by $|\varphi'|^2$ before there has been an appreciable displacement of q_j from 0. ϵ_g has been replaced by ϵ_u, giving an additional "force" $-\epsilon_j$ on q_j. In the case considered in Fig. 2 $\epsilon_j=-\omega_j^2\Delta q_j$. Hence the total potential energy of the lattice relative to point b is $\frac{1}{2}\omega_j^2 q_j^2+\epsilon_j q_j$ and its minimum appears at $q_j=-\epsilon_j/\omega_j^2$ in agreement with (3.23). As soon as the force on the q_j'th mode has changed, its equilibrium value has as well, although the ions are not at $-\epsilon_j/\omega_j^2$.

During the shift from b to c, $\Delta\epsilon$ *decreases* by $-\epsilon_j\Delta q=(\epsilon_j^2/\omega_j^2)$, while the potential energy of the lattice *increases* by $\frac{1}{2}\epsilon_j^2/\omega_j^2$, thus giving a total decrease of $\frac{1}{2}\epsilon_j^2/\omega_j^2$. Hence the third term of (3.25)* is composed of two effects, the decrease of electronic energy and the increase of lattice energy. The simplicity of the interpretation arises because of the assumption that the restoring forces are not affected by the jump of the electron in the trap.

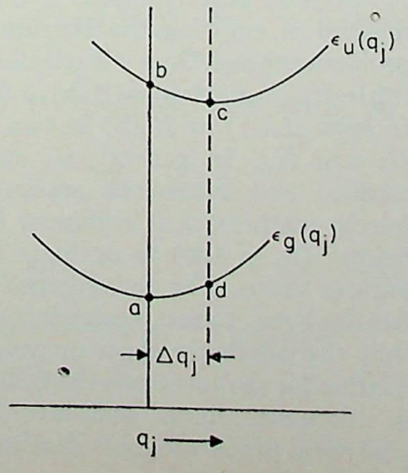

FIG. 2. Plots of ϵ_g and ϵ_u against q_j.

Quantum mechanics (still assuming that $\epsilon_{jj}=0$) only slightly modifies the picture. The stationary states are represented by horizontal lines since normal vibrations have kinetic as well as potential energy. The most probable transitions arise when the classical turning points of the upper and lower states occur for the same value of q_j. While this is the most probable, it is not the only one; indeed, the probability of "nonvertical" transitions explains the shape of the emission and absorption bands in solids.

The theory developed in Sec. 3 is now used to define the various types of activation energies. Neglecting the broadening due to the emission or absorption of phonons, the zero-point energy, and limiting our consideration to 0°K, we may define the following: activation energy for emission of a photon—E^e—$(c-d)$; activation energy for absorption of a photon—E^a—$(a-b)$; thermal activation energy which is the same for emission and absorption—E^t—$(a-c)$. The a, b, c, and d refer to Fig. 2.

As has been stressed previously, the Stokes' shift, which is the difference between E^e and E^a, is related to the third term of (3.25). After an absorption (from a to b), the force $-\epsilon_j$ is added, and the system relaxes by going to c. For $\epsilon_{jj}=0$, the stored energy after an emission equals the stored energy after an absorption, i.e.,

$$\epsilon_g(-\epsilon_j/\omega_j^2)-\epsilon_g(0)=\epsilon_u(0)-\epsilon_u(-\epsilon_j/\omega_j^2). \qquad (4.1)$$

In (4.1) the arguments of ϵ_u refer to values of q not Q. Summarizing, the absorption activation energy includes the readjustment energies in both the upper and ground states; the emission activation energy excludes both, while the thermal includes the readjustment energy in only one state.

Although (4.1) was derived by considering the displacement of only one mode, it is quite general because ϵ_g and ϵ_u are functions only of the q's and not of the path taken. The displacements can be compared one by one to show that for an actual trap the total stored energy is the same in both states. In general then, one may write

$$E^e+2\delta E=E^t+\delta E=E^a \qquad (4.2)$$

where δE is the readjustment energy $(\frac{1}{2})\sum_j \epsilon_j^2/\omega_j^2$, or

$$E^t=E^a-(1/2)(E^a-E^e)=(1/2)(E^a+E^e). \qquad (4.2a)$$

If $E^e=0$, $E^t=\frac{1}{2}E^a$; hence, in general

$$E^t\geqslant(1/2)E^a \quad (\text{for } \epsilon_{jj}=0). \qquad (4.2b)$$

In some problems we may be able to introduce an

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

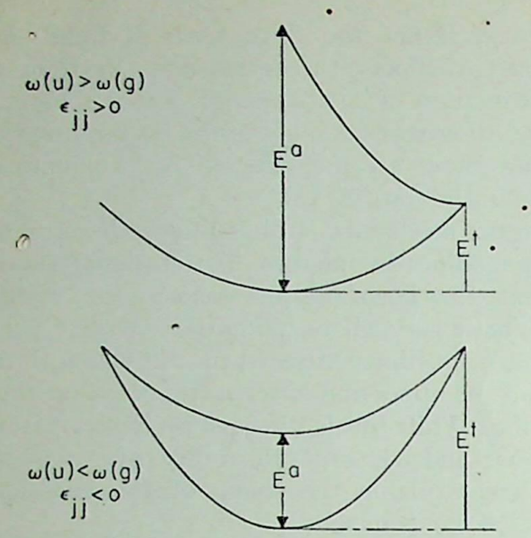

FIG. 3. Effects of ϵ_{jj} on E^a and E^t.

effective frequency (Secs. 9 and 10). In this case

$$\delta E=\tfrac{1}{2}\sum_j \epsilon_j^2/\omega_j^2=\hbar\omega\{\tfrac{1}{2}\sum_j \epsilon_j^2/\hbar\omega_j^3\}=\hbar\omega S \qquad (4.3)$$

where ω is the effective frequency, defined by (4.3), and

$$S=\tfrac{1}{2}\sum_j \epsilon_j^2/\hbar\omega_j^3, \qquad (4.3a)$$

the Huang-Rys factor. One may measure S directly for some transitions (Sec. 11). It is the ratio of the stored energy at b to the average effective phonon energy. For the F center in KCl, $S\approx 30$ (K4).

A relaxation of (4.2) occurs when $\epsilon_{jj}\neq 0$. When $\epsilon_{jk}(j\neq k)$ is small compared to ϵ_{jj}, the effect of the second derivative is to shift the frequencies of the modes. One may speak of a frequency shift superimposed on a displacement of the equilibrium position. Now (4.2b) does not apply, and E^t can be much smaller than $\frac{1}{2}E^a$. In other cases it can be even larger than E^a, as illustrated in Fig. 3,§ where only one mode is considered. If $E^t\ll E^a$, ϵ_{jj} must be of the order of ω_j^2. For $\epsilon_{jj}<0$, one obtains the strange case where $E^a<E^t$. However, the author knows of no such case in nature.

In the self-trapping calculations made by Seitz and the author (M6) for NaCl, items 2 and 3 of Sec. 2 were not considered; hence, $E^t=\frac{1}{2}E^a$. This gives 0.34 ev for E^t, not the value originally reported. The error arises from an erroneous formulation of Feynman's theorem (Eq. 3.16). The agreement between the calculation of Fröhlich, Pelzer, and Zienau (F3) and the reported value of E^t (i.e., 0.13 ev) must be fortuitous. The author believes that higher-order terms than ϵ_j must be included. Further, the mobility of the trap has to be included; hence the value 0.34 ev is a very preliminary one.

In view of the values of E^t and E^a for the F' center, the ϵ_{jj}'s must almost equal ω^2's for the local modes which cluster about negative-ion vacancies. The upper F' state corresponds to an F center and an electron in the conduction band. The lower state corresponds to two electrons in a negative-ion vacancy. To the approximation of interest here we may assume that the free electron does not interact with the modes. $\Delta\epsilon(\mathbf{R})$ of Eq. (3.17) is simply the binding energy of the second electron in the F' center. Since there is a radical difference in the upper and lower states, the assumption of $\epsilon_{jj}\approx\omega_j^2(g)$ seems plausible. The author finds it hard to believe that a corresponding situation exists for a hole trapped at a positive-ion vacancy. One assumes that it possesses two bound states. This is Seitz's model for the V_1 band in KCl and KBr. The hole must be spread out similar to an electron in the F center. Transitions of the hole from an excited to a ground state could influence the vibrational frequencies but hardly enough to change the activation energy from 3.0 ev to 0.23 ev. Our present knowledge of the V centers is so meager that the possibility of an alternate interpretation of the experiment should not be overlooked.

§ *In Fig. 3, the problem of the intersection of the potential curves has not been considered.*

5. PROPERTIES OF THE TOTAL HAMILTONIAN

In Sec. 3 a theory was developed which is completely general, provided one may use the Born-Oppenheimer technique. In this section we compare this development to alternate formulations of the problem in order to contrast the ideas. We also compare the development of Sec. 3 with some problems in electrodynamics, in particular, to contrast the behavior of phonons and photons.

In complex systems one likes to split the Hamiltonian into parts which interact only slightly. Thus, in electrodynamics, it is divided into the radiation field $H_{\rm rad}$, the part related to the charged particles $H_{\rm el}$, and the interaction term $H_{\rm int}$, which relates the electrons to the photons. One usually develops expressions for $H_{\rm rad}$ and $H_{\rm el}$ without regard to each other. The introduction of an electron in a vacuum does not affect $H_{\rm rad}$, nor does the introduction of black-body radiation affect $H_{\rm el}$. When one considers a trapped electron in an electromagnetic field one adds $H_{\rm int}$ to $H_{\rm rad}+H_{\rm el}$ without modifying either.

The solid state problem is more complex, and the method of splitting the Hamiltonian depends on the problem at hand. Once Ψ is selected, the term corresponding to $H_{\rm int}$ is given by (3.12b) or (3.13b). The problem is to split $H_0(A)$ or $H_0(S)$ in two. These we denote by H_e and H_L. In general, H_e and H_L are intimately coupled and cannot be separated. One may use a purely mathematical argument like Born and Oppenheimer (B, p. 166) to evaluate the importance of the various terms. The convergence of the approximation has not been studied, however. Crude calculations show that the adiabatic approximation must be used with caution for shallow traps (M4). The splitting procedure is discussed in a semi-intuitive manner; further analytical proofs are most desirable.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

(a) Trapped Electron

For an electron trapped at a point imperfection, we may use (3.1) or a form which is related more closely to the way actual calculations are made. For the latter purpose we define the impurity center Hamiltonian. With proper care one may make the treatment completely rigorous. Thus we write

$$H=t+T+V_L(\mathbf{R})+V_I(\mathbf{R})+V_e(\mathbf{R},\mathbf{r}). \quad (5.1)$$

Here t is the kinetic energy of the trapped electron; V_L+V_I is the interionic or interatomic potential; $V_e(\mathbf{R},\mathbf{r})$ is the potential energy due to an excess electron at $\mathbf{r}$ when the ions (or atoms) are at $\mathbf{R}$.

It is convenient for pedagogical purposes to split V_L+V_I into two parts. V_L is the potential energy for the perfect lattice, and V_I arises from the point imperfection. Thus, in the case of the F center, V_I is due to the negative-ion vacancy. Mott and Littleton considered this problem (M12), so one may call V_I the Mott-Littleton term. In the more conventional treatment, V_L+V_I arises from the coulombic and repulsive forces of the crystal. In treatments using the Born-Oppenheimer technique, it arises from the eigenvalue of an electronic Hamiltonian which includes all the electrons except the trapped one (B, p. 173).

First, deep traps are considered; hence, we are required to use the adiabatic approximation. Equation (3.13) gives

$$(H_L+H_e)\varphi(\mathbf{R})\chi=H_0(A)\varphi(\mathbf{R})\chi$$
$$=\varphi T\chi+(t+V_L+V_I+V_e)\varphi\chi, \quad (5.2)$$

$$H_1(A)=H-H_0(A). \quad (5.2a)$$

There is a striking contrast between our problem and a photon field. The splitting in electrodynamics is done purely classically and in an elegant manner. Here we have had to introduce quantum mechanical operators and further assume an approximate wave function. How does one split H_0 into two parts?

Following the development in Sec. 3, we expand about $\mathbf{R}_n$ defined by

$$\left\{\frac{\partial}{\partial X_\alpha(k)}[\Delta\epsilon_n+V_L+V_I]\right\}_{\mathbf{R}_n}=0. \quad (5.3)$$

$\Delta\epsilon_n$ is an eigenvalue of $t+V_e(\mathbf{R},\mathbf{r})$. We split $H_0(A)$ by writing

$$H_L=T'+V_L+V_I+\Delta\epsilon_n(\mathbf{R})-\Delta\epsilon_n(\mathbf{R}_n) \quad (5.4)$$

and

$$H_e=t+V_e. \quad (5.5)$$

T' means that T only operates on χ. We note that

$$H_0\neq H_L+H_e. \quad (5.6)$$

When the sum operates on $\varphi\chi$ an extra function $\Delta\epsilon_n(\mathbf{R})-\Delta\epsilon_n(\mathbf{R}_n)$ appears. H_L includes approximately the cohesive energy of the distorted crystal.‖

The modes defined by (5.3) and (5.4) depend on the state of the electron due to the presence of $\Delta\epsilon_n$. Using the foregoing development, we may understand the various simplifications that have been made.

(1) The phenomenological approach (a) ignores the presence of V_I and (b) makes a crude approximation of the actual Hamiltonian by assuming that the equation

$$\{H_L-V_I-\Delta\epsilon_n(\mathbf{R})+\Delta\epsilon_n(\mathbf{R}_n)\}\chi=\epsilon_v\chi \quad (5.7)$$

gives pure longitudinal and pure transverse optical modes. It further assumes that the lower branches are pure acoustical.

These extreme simplifications are inadequate for some problems involving normal modes in alkali halides. The interaction between the trapped electron and the phonons is obtained by adding $\Delta\epsilon_n$ to (5.7); namely, one requires solutions of the following equation:

$$\{H_L-V_I\}\chi=\epsilon_v\chi. \quad (5.8)$$

In principle the inclusion of $\Delta\epsilon_n$ leads to no difficulties, and the method developed in Sec. 3 can be employed. Meyer has developed a perturbation scheme using V_e. This, however, leads to the omission of some terms. In Appendix II we compare both methods.

(2) The local modes approach: One assumes that the eigenequation

$$H_L\chi=\epsilon_v\chi \quad (5.9)$$

gives two types of modes, q_i, which are local, and q_c, which pertain to the perfect crystal. For this approach to be valid, $\Delta\epsilon_n$ must be independent of the q_c. If $\Delta\epsilon_n$ is only a function of a single localized mode then we have the CC model. The $\Delta\epsilon$'s can again be used to calculate the effect of the trapped electron on the modes. *A priori*, there is no clear reason for believing that $\Delta\epsilon_n$ will be independent of the q_c's. Hence, there is no apparent reason to assume that $\Delta\epsilon_n$ will not be a function of the q_c's. Only extremely complex calculations, not available at present, could tell the exact form of $\Delta\epsilon(q_i,q_c)$. One may resolve this problem somewhat by obtaining equations for the shape of absorption and emission bands in solids with adjustable parameters. These parameters can be evaluated by analysis of the experimental data. This, in turn, will give basic information regarding the relations among $\Delta\epsilon_n$, q_c, and q_i. Part II of this paper is devoted to this problem.

(b) Free Electron

Consider next a free electron in a metal or semiconductor. Two arguments suggest that the Born-Oppenheimer technique should not be used. First, consider the effect a free electron at $\mathbf{r}$ has on the modes. Its behavior is described by means of a wave packet

‖ Approximately because we use $\mathbf{R}_n$ defined by Eq. (5.3) instead of the values of $\mathbf{R}$ determined by minimizing V_L or V_L+V_I.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

made from Bloch functions. The electron proceeds in a straight line for about 200 A and then gets reflected through an angle. If the electron has the energy of 3 ev (approximately the Fermi level of a metal) it collides with the lattice every 2×10^{-14} sec. It is not confined to a local region, but wanders in random fashion, so that an average effect over a period of vibration is meaningless. Analytically, for a pure Bloch function, ϵ_j equals zero, so such an electron does not exert a force on the normal modes as shown below. Therefore, one splits the system's Hamiltonian as follows ($V_I=0$)

$$H_L=T+V_L(\mathbf{R}) \tag{5.10a}$$

$$H_e=t+V_e(\mathbf{R}_L) \tag{5.10b}$$

and

$$H_1=V_e(\mathbf{R})-V_e(\mathbf{R}_L) \tag{5.10c}$$

to obtain the usual theory (W4-Chap. IX). The normal modes about $\mathbf{R}_L$ are determined from V_L. Here another assumption is made, that one should use $\varphi(\mathbf{R}_L)$ rather than $\varphi(\mathbf{R})$. The continuously readjusting wave function requires a type of kinetic energy, and one suspects that the loss in potential energy does not compensate for this gain (M4).

The distinction between the static and the adiabatic approximation is academic, since, as Haug (H2) has shown, that first-order perturbation theory gives the same results for both. The treatment assumes that one does not use the Born-Oppenheimer technique for the free electron—that is, that H_L determines the q's. This requires that $\epsilon_j(\mathbf{R}_L)=0$. Proof of this relation for a Bloch electron is now given.

The interaction between an electron and the lattice in the conduction band has the form

$$H_1=\textstyle\sum_j a_j\Lambda_j, \tag{5.11}$$

where the Λ_j's are determined from (5.10a). To a sufficient approximation we write

$$a_j=\text{const}\,\exp(i\mathbf{k}_j\cdot\mathbf{r}) \tag{5.12}$$

where $\mathbf{k}_j$ is the wave-number vector of the jth mode. The Bloch function for a conduction electron may be written in the form

$$\varphi_p=u_p(\mathbf{r})\,\exp(i\mathbf{p}\cdot\mathbf{r}) \tag{5.13}$$

where $\mathbf{p}$ is the momentum vector and u_p has the periodicity of the lattice. Hence from (3.16) it follows that

$$\epsilon_j=\langle\varphi_p|\,a_j\,|\varphi_p\rangle=\text{const}\int u_p{}^2\exp(i\mathbf{k}_j\cdot\mathbf{r})d\tau=0 \tag{5.14}$$

since u_p is periodic. This shows that the Λ_j's describe the true modes.¶ This argument also applies to nonpolar semiconductors.

This proof as it stands should apply to polar crystals as well. Detailed considerations show that this development is incomplete. This follows because some ϵ_{jj} are zero in spite of the fact that $\Delta\epsilon_n(\mathbf{R})$ is not small. For this case H_1 has a major influence on the q's, and the presence of the electron may generate a new set of modes. Here the problem does not correspond to the one in electrodynamics.

Applying this approach, Eq. (5.10), to deep traps where the electron's kinetic energy is large, (5.14) does not hold, and exceptionally large values of the interaction are obtained, simply because the q's derived from (5.10) are not the appropriate ones. These χ's form an orthogonal set, although a force $-\epsilon_j(\mathbf{R}_L)$ remains on the nuclei at $\Lambda_j=0$.

(c) Comparison with Quantum Electrodynamics

Coming now to some general comparisons between quantum electrodynamics and the theory developed here, no equation in quantum electrodynamics corresponds to (3.4a). First, consider case b where all the $\epsilon_j(\mathbf{R}_L)$'s are zero and the Λ's are the true modes. Hence H_{rad} corresponds to H_L, H_{el} corresponds to H_e, and H_{int} corresponds to H_1. The frequency and wavelength of the photon modes are determined for free space and are not influenced by the electrons, although their number is determined in part by electronic transitions. The number of phonons is also determined by the electronic state, if we use time dependent perturbation theory, although the q's are obtained from H_L. The polaron problem in semiconductors and metals corresponds to the self-energy problem in electrodynamics. This is also true for many optical problems in valence semiconductors, i.e., such as the band-to-band transition in germanium, silicon, and diamond. Here the normal modes do indeed behave in a manner similar to photons, and the word "phonons" is most appropriate.

This is to be contrasted to the situation where method (a) should be used. The term which mixes the electronic and normal mode wave functions or causes transition is $H_1(A)$ of (5.2a). The ϵ_j's and ϵ_{jj}'s have no counterpart in quantum electrodynamics. They generate a new set of q's for every electron level and cause an essential difference between the two fields. Their presence makes multiphonon processes natural in some solids. In this case, optical problems are similar to those occurring in diatomic molecules (Part II). The similarity between phonons and photons breaks down. If one applies method (b) to polar crystals, there is no simple way to separate the energy associated with the poor choice of the modes and that caused by $H_1(S)$.

Thus we have two types of problems in phonon-dynamics. In one the ϵ's can be ignored and use can be made of the tools of modern electrodynamics. In the other, we are in a different domain, where the ele-

¶ One may arrive at the expression for ϵ_j in a more rigorous manner. In general $\langle\varphi_q|H_1|\varphi_p\rangle\neq0$ only if $\mathbf{p}-\mathbf{q}\pm\mathbf{k}=0$ [W4, Eq. (9.3.3) with $\mathbf{g}_b=0$]. Here $\mathbf{p}=\mathbf{q}$; hence, for $\mathbf{k}_j\neq0$, $\epsilon_j=0$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

mentary concepts of electrodynamics do not serve as a guide. The first situation is in a sense a "special" case.

6. CONCLUSIONS OF PART I

1. By the use of the Born-Oppenheimer method, we have shown what effects electron transitions have on the normal modes of vibration. The problem has been formulated in a new manner to show the interrelation of the various terms. The two major effects are (a) a shift in the equilibrium position of the normal modes—first-order effect; (b) a change in the frequencies of vibration—second-order effect. The analytical reason for these shifts is shown and related to the change in the electronic binding energies of traps. The relations which are derived from the microscopic Hamiltonian are completely general. It was indicated why one would not expect the calculations made by Huang and Rhys, by Pekar, and by Lax to apply to an F center. To obtain an accurate theoretical expression, greater care must be taken in the use of various expansions.

2. Various activation energies are defined and general relations obtained between them. These impose restrictions on the interpretation of some experiments done on color centers.

3. A comparison has been made of quantum electrodynamics and phonondynamics. Terms not present in the former arise. They account for multiphonon processes. These additional terms play a very important role in the shape of optical absorption and emission bands. They may enter into the polaron problem. The electron in the conduction band of some polar solids may create new local modes about itself. These local modes do not appear in electrodynamics, hence the polaron problem in some crystals is not equivalent to problems in electrodynamics. These terms make it possible for a hole to be self-trapped, as indicated by the experiments of Castner and Kanzig (C1). To understand the stability of some of the new types of centers, the molecular color centers, we must examine the phonon-electron Hamiltonian discussed here in fuller detail.

Part II—Broadening of Absorption Lines Due to Multiphonon Processes

7. INTRODUCTION TO PART II

In the following sections the theory developed in Part I is applied to the broadening of absorption bands in solids. We only consider transitions between two bound states. The breadth of a line may be due to several causes.

(a) One is the Heisenberg principle which requires an uncertainty in the energy of a level, provided its lifetime is finite. An alternate way of looking at this problem is to use higher-order terms in the standard time-dependent perturbation theory (H3, p. 181). This explains the breadth of the hydrogenic lines at low pressure. The breadth of lines due to this effect should be very roughly of the order of that observed in atoms.

TABLE II. Breadth of absorption lines in ev.

Atomic	
One of the H_α lines of hydrogen	3×10^{-6}
A very wide atomic line of CuI ($^4F_{\frac{5}{2}}-{}^4D_{\frac{3}{2}}$ at 4540 A)	6×10^{-4}
Solids	
The 278 cm^{-1} line of B doped Si	7×10^{-4}
The F center breadth in KCl at 0°K	0.16
The F' center breadth in KCl	about 1
A narrow band in LiF (P5)	0.01
Energy of one optical phonon	0.01–0.08

(b) Broadening is also caused by the interaction between centers. We must assume that there is more than one trap in a solid so that (5.1), which applies only to an individual imperfection, does not contain the whole Hamiltonian. Their sum does not form the total Hamiltonian, for one must consider interactions between centers. Without these additional terms, ϵ_u represents a highly degenerate level, since any imperfection can be excited. With the interaction terms, the degeneracy of ϵ_u is removed, and the excited states spread out into a narrow band. Since no detailed calculation has been made, it is not known whether the degeneracy of ϵ_u can be completely removed. If a crystal has 5×10^{16} centers per cc, the mean separation is 270 A. This type of interaction must be small in polar solids, since 270 A is large compared to the spread of the electron wave functions. For example, the excited state of the F center in KCl does not extend beyond 13 A (Smith, S6). The interaction may not be small if the imperfection is such that the spread in the wave function is of the order of the distance between centers.

(c) Although this effect may make a small contribution to the broadening of an absorption line in solids, our interest is in the fact that during an optical transition no strict selection rules apply to the v_j's. If $\epsilon_j=\epsilon_{jj}=0$, strict rules would apply, and this effect would not make a contribution to the problem.

Effects (a) and (b) are essentially temperature independent, while (c) depends strongly on the temperature.

In view of the complexity of the problem, equations are derived with parameters which are to be evaluated experimentally. This is the first necessary step, since at present our knowledge is far too meager to attempt exact *a priori* calculations. Some experimental facts will be presented before embarking on the theoretical details.

The width of lines varies over a large range. Some typical values are given in Table II. Thus the width of some lines in solids approaches the broadest found in atomic spectra. In general, lines in solids are considered broader, however. In polar crystals some bands are very much wider, and the absorption or emission of a

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

single phonon will not explain the phenomenon. The marked temperature dependence of the shape of some lines strongly suggests that (c) can dominate the others. Detailed studies (M5, K4) support this conclusion.

The theory developed here does not apply to the F' band since the upper state is not bound. It is not completely clear why some bands in polar materials are extremely narrow. One may simply assume that certain parameters, to be derived, are very small. On the other hand, more complex concepts may be involved, such as the breakdown of the Born-Oppenheimer technique; further studies are required. The theory developed applies to bands whose width is approximately equal to the F center and is temperature dependent.

Experimentally, the absorption, α, is measured as a function of the wavelength or the photon energy ϵ (in ev). The observed $\alpha(\epsilon)$'s are not simple analytical curves; hence a way must be found to characterize them. We may in general define: ϵ_m, the value of ϵ where α has its maximum value, α_m; ϵ_r is where α has half its maximum value on the red side of ϵ_m, and ϵ_v is the corresponding point on the violet. Further useful definitions follow:

the moments— $$M_n=\int_0^\infty \alpha(\epsilon)\epsilon^n d\epsilon \tag{7.1}$$

the average— $$\bar{\epsilon}=M_1/M_0 \tag{7.2}$$

$$m^2=\frac{1}{M_0}\int_0^\infty (\epsilon-\bar{\epsilon})^2\alpha(\epsilon)d\epsilon \tag{7.3}$$

and the half-width— $$H=\epsilon_v-\epsilon_r. \tag{7.4}$$

In general,

$$m^2=(M_2/M_0)-\bar{\epsilon}^2. \tag{7.5}$$

The absorption is due to upward transitions induced by the vector potential of the light which falls on the crystal. To relate the measured absorption at photon energy ϵ to the transitions, four factors must be considered.

(1) The vector potential at the imperfection has to be related to the intensity of light falling on the crystal. Lorentz suggested a way of doing this. It is not known whether his theory applies rigorously to traps in solids and deviations from his simple equation would not be surprising. In any case the Poynting vector (the light intensity) is proportional to the square of the vector potential at the imperfection.

(2) The second factor is due to the φ's which give matrix elements. The expression may be simplified by the introduction of an oscillator strength, f. Classically, the second item contains no unknown since f equals unity. Quantum mechanically, the problem requires exact wave functions, which at present are unknown. Most probably, we shall have to introduce the f factor empirically for some time to come.

(3) The imperfection concentration.

(4) Finally, one must consider the shape factor. This can be done by multiplying the usual atomic absorption equation, item (2), by a function $G_n(\epsilon)$. G_n arises from items (a), (b), and (c) considered previously. In all cases studied so far, G_n has the property $\int G_n(\epsilon)d\epsilon \cong 1$.

The measured absorption at ϵ is the product of the above four factors. If one could make exact calculations, the impurity concentration could be treated as an unknown and computed from a single point, ϵ. Even without an exact calculation, one might evaluate the factor associated with (1) and (2) from experimental data and obtain the concentration with the use of a single constant. This would require a detailed knowledge of G_n, which is lacking. The G_n can be eliminated by an integration over ϵ. This procedure is impractical in many cases, for one cannot measure the absorption at the wings of the band (due to overlapping from other absorption bands). The integration technique is also extremely lengthy. Many years ago Smakula suggested replacing $\int \alpha(\epsilon)d\epsilon$ by a product of α_m times H. This requires the introduction of a constant a_s such that $a_s G_m H=1$, where G_m is the peak value of G.

To illustrate this procedure, let us assume that G_n has the triangular shape, i.e.,

$$\begin{aligned} G_n &= 0 && \text{for} \quad \epsilon > a \\ &= (1/H)(a-\epsilon/a-\epsilon_m) && \text{for} \quad a > \epsilon > \epsilon_m \\ &= (1/H)(\epsilon-b/\epsilon_m-b) && \text{for} \quad \epsilon_m > \epsilon > b \\ &= 0 && \text{for} \quad b > \epsilon. \end{aligned} \tag{7.6}$$

The area under G_n is unity. The integration over the frequency equals $G_m H$ and $a_s=1$ for the shape given by (7.6). Hence, the product $G_m H$ or $\alpha_m H$ eliminates the fourth factor. The advantage of this procedure is that the temperature dependence of H seems to be eliminated.**

The essence of Smakula's famous equation is the substitution of $G_m H$ for $\int G(\epsilon)d\epsilon$, not the exact form of $G_n(\epsilon)$. Therefore we refer to the general equation by his name and call a_s Smakula's constant. In this equation a_s is always multiplied by two factors arising from (1) and (2); hence the actual value of a_s is of little experimental importance. Nevertheless, a_s is a measure of the shape of an absorption band, as are the variables defined in Eq. (7.1) to (7.5).

It is useful to determine H, m, and a_s for several types of $G_n(\epsilon)$, namely,

The Gaussian

$$G_n=\frac{a}{\sqrt{\pi}}\exp\{-a^2(\epsilon-\epsilon_m)^2\}. \tag{7.7}$$

** "Seems to be," since there is practically no experimental data to support or refute this assumption.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Hence,

$$H(G)=\frac{1}{a}[4\ln 2]^{\frac{1}{2}}. \tag{7.7a}$$

Further

$$m^2=(1/2a^2)=(1/8\ln 2)H^2=(1/5.545)H^2 \tag{7.7b}$$

and

$$a_s(G)=(1/G_mH)=[\pi/4\ln 2]^{\frac{1}{2}}=1.0645. \tag{7.7c}$$

The Lorentzian

$$G_n=\frac{b}{\pi}\frac{1}{[1+b^2(\epsilon-\epsilon_m)^2]} \tag{7.8}$$

Now

$$H(L)=(2/b) \tag{7.9a}$$

and

$$a_s(L)=(\pi/2)=1.5708. \tag{7.9b}$$

M_2 does not exist for (7.8).

The Double Gaussian

G_n might be made of two Gaussians, one for the violet side with $a=a_v$ and another for the red side, with $a=a_r$. Then

$$G_m=(2/\sqrt{\pi})[(1/a_r)+(1/a_v)]^{-1}, \tag{7.10}$$

$$H(DG)=(\ln 2)^{\frac{1}{2}}[(1/a_r)+(1/a_v)], \tag{7.11a}$$

$$m^2=\tfrac{1}{2}[(1/a_r)+(1/a_v)]^{-1}\times[(1/a_r^3)+(1/a_v^3)], \tag{7.11b}$$

and

$$a_s(DG)=a_s(G)=1.0645. \tag{7.11c}$$

Various attempts have been made to describe the shape of the absorption band associated with F centers and all three types have been considered. One of the most successful is the double Gaussian. For this curve a_s is the same as for the single Gaussian.

The Pekarian

This curve is discussed in Sec. 9 and Appendix IV. To obtain $a_s(P)$, numerical integration techniques were used, since the analytic form is complex. It actually depends on H. However, unless the half-width is very small,

$$m^2=H^2/5.57 \tag{7.12a}$$

and

$$a_s(P)=1.07, \tag{7.12b}$$

which agrees with Eqs. (7.7b) and (7.7c). A Pekarian curve resembles a double Gaussian, so that the similarity of $a_s(P)$, $a_s(G)$, and $a_s(DG)$ is not surprising.

In Smakula's original derivation $a_s(L)$ was used. In recent years experimental studies indicate that the Gaussians or double Gaussians give better agreement with the observed curves. Dexter has suggested that one might replace $a_s(L)$ by $a_s(G)$. There are good arguments for this change. The absorption shapes, however, are not true Gaussians, and the suggestion simply means that we replace one empirical constant with another without gaining any fundamental information. There is some evidence that the band shape is Pekarian.

Since in Smakula's equation a_s is always multiplied by two other factors, the actual value of a_s is of little experimental importance. The danger in making the change is that confusion will result. The day may come when one will know the true form of G_n and have a correct expression for a_s. As this day has not yet arrived, the standard form of Smakula's equation is preferable.

8. GENERAL FORMULATION OF ABSORPTION PROBLEM

In this section the absorption problem is formulated in general. The next two sections discuss the shape and moments. Since deep traps are to be considered, the adiabatic approximation must be used. The electron-phonon interaction term, i.e., (3.13b), will be ignored. The Hamiltonians of the solid can therefore be written in the forms: for the ground state

$$H_g=\epsilon_g(\theta)+T_g'+V_g \tag{8.1}$$

or

$$E=\epsilon_g(\theta)+\textstyle\sum_j \hbar\omega_j(g)(v_j+\frac{1}{2}), \tag{8.1a}$$

while for the excited state

$$H_u=\epsilon_u(\theta)+T_u'+V_u \tag{8.2}$$

or

$$E'=\epsilon_u(\theta)+\textstyle\sum_j \hbar\omega_j(u)(v_j'+\frac{1}{2}), \tag{8.2a}$$

where v_j is the vibrational quantum number of the jth mode when the electron is in the ground state, while v_j' corresponds to the upper state; ϵ_g and ϵ_u are evaluated at $\mathbf{R}_g$ and $\mathbf{R}_u$, (3.19a) and (3.19b) $H_{g,u}$ is an operator, while E is the total energy, (3.14a). V_g and V_u are $\epsilon_g(\mathbf{R})-\epsilon_g(\mathbf{R}_g)$ and $\epsilon_u(\mathbf{R})-\epsilon_u(\mathbf{R}_u)$, respectively [see Eq. (3.4)].

Effects of thermal expansions are not included in the theory of Part I. The thermal expansion of the crystal arises from the dependence of the vibrational frequencies on the volume (Slater, S5, p. 199). In principle, the thermal expansion may influence all the variables. It is believed that the primary effect of the temperature (θ) is on ϵ_g and ϵ_u.

To arrive at an expression for the absorption coefficient, we start with the standard equation for the energy absorbed by an atom when light falls on it (2 of Sec. 7). This expression must be corrected for the presence of the medium and for various broadening effects, as discussed in the last section (1 and 4). Since Dirac's delta functions are used, special care must be employed. First-order perturbation theory gives the following expression for the energy absorbed by an atom in a

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

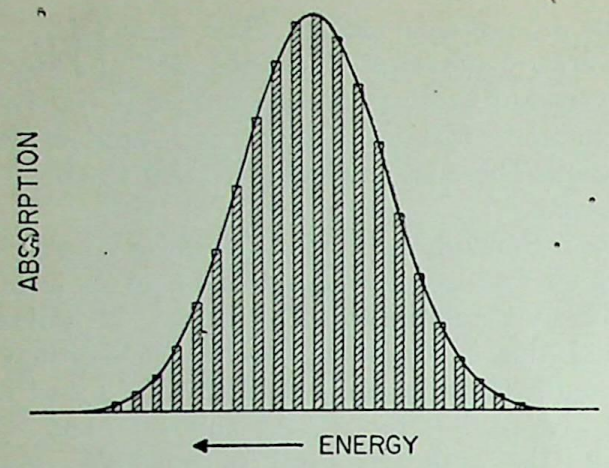

FIG. 4. Schematic diagram showing the broadening due to the emission or the absorption of phonons.

vacuum (H3, p. 180):

$$s_{\text{atom}}=\frac{4\pi^2}{3}\frac{e^2}{\hbar c}\nu|\{\langle\Psi'(A)|\mathbf{r}|\Psi(A)\rangle\}|^2 I_\nu, \qquad (8.3)$$

where ν is the angular frequency of the absorbed light††; $\Psi'(A)$ and $\Psi(A)$ are the total wave functions for the ground and excited states, Eq. (3.11); and I_ν is the intensity of the light per unit angular frequency interval, i.e., the energy of the light which falls on the crystals in the angular frequency interval $\Delta\nu$ is $I_\nu\Delta\nu$.

In a medium, the following modifications must be made.

(1a) If n_0 is the high-frequency dielectric constant, the intensity I_ν (Poynting vector) is $(cn_0F^2/4\pi)$. Since the transition is caused by F^2, (8.3) must be divided by n_0.§§

(1b) The space average field must be replaced by the local field. Since they are proportional to each other, we introduce a constant bn_0. For a Lorentz local field $b=(1/9n_0)(2+n_0^2)^2$ (B, p. 100).

(2) As discussed, lines have a finite width.

(1a) and (1b) correspond to 1 of Sec. 7. (2) corresponds to the broadening due to the uncertainty principle and the interaction between neighboring centers. If (8.3) is multiplied by b, the effects of (1a) and (1b) are included.

(2) requires the introduction of the function $g(\nu)$ with the following properties; it peaks at

$$\nu=[E'-E]/\hbar \qquad (8.4)$$

and

$$\int_0^\infty g(\nu)d\nu=1. \qquad (8.5)$$

The g does not include the effects of the ϵ_j's and ϵ_{jj}'s and is not the same as G_n. Figure 4 illustrates the problem. There is an over-all absorption band and a fine structure. We may expect to observe the fine structure only if the half-widths of the g's are less than the energy of one phonon (i.e., $\hbar\omega$). Figure 4 assumes that one is dealing with a single phonon frequency. When a center interacts with phonons of several frequencies, i.e., if there is dispersion, the ϵ_j's and ϵ_{jj}'s can cause a broadening of the "lines" shown in Fig. 4. This problem has been discussed by Krivoglaz and Pekar (K5). There seems to be no simple way to separate this effect from those discussed in Sec. 7. This effect is not considered further here.

We now digress slightly to indicate how the trap-trap interaction produces a broadening. The breadth of an electron-spin resonance line also arises from two effects: one is because of the interaction between the spins (spin-spin), and the other is because of the interaction of the electron with the magnetic moments of the surrounding nuclei (hyperfine). The hyperfine interaction often has a much larger effect. The problem is thus similar to the one considered here. Strangely enough, we have a much better understanding of the broadening problem in the newer field (electron-spin resonance).

For this development the solid is considered to be a large molecule of unit volume. There will therefore be N imperfections. We ignore the lattice vibrations, hence denote by $\mathbf{R}_j$ the rest position of the jth imperfection, and by $\mathbf{r}_j$ the position of its electron (relative to $\mathbf{R}_j$). Again two bound states per trap are assumed. The total ground state eigenfunction has the following form in the zeroth approximation, where the interactions between imperfections are ignored,

$$\Phi_0(g)=\Pi^j\varphi(\mathbf{R}_j+\mathbf{r}_j). \qquad (8.6)$$

(8.6) uses the Hartree approximation (S2, p. 234), while the excited state is of the form

$$\Phi_0(u_1k)=\varphi(\mathbf{R}_1+\mathbf{r}_1)\cdots\varphi(\mathbf{R}_{k-1}+\mathbf{r}_{k-1})\times\varphi'(\mathbf{R}_k+\mathbf{r}_k)\varphi(\mathbf{R}_{k+1}+\mathbf{r}_{k+1})\cdots\varphi(\mathbf{R}_N+\mathbf{r}_N). \qquad (8.7)$$

It is N-fold degenerate, since any imperfection can be excited.

We next consider two perturbations: (1) due to the optical waves and (2) due to the imperfection-imperfection interaction. The first has the form [H3, Eq. (13.7)],

$$\sum_j(e/mc)\mathbf{p}_j(e)\cdot\mathbf{A}(\mathbf{R}_j+\mathbf{r}_j), \qquad (8.8)$$

where $\mathbf{p}_j(e)$ is the electron's momentum and $\mathbf{A}$ is the vector potential. If one combines (8.6), (8.7), and (8.8) with the usual theory of absorption (H3, p. 143 and p. 179), the following transition matrix is obtained,

$$|\langle\Phi_0(u,k)|\mathbf{R}_{\text{eff}}|\Phi_0(g)\rangle|^2 \qquad (8.9)$$

where

$$\mathbf{R}_{\text{eff}}=\sum_j\mathbf{r}_j\exp(-i\boldsymbol{\kappa}\cdot\mathbf{R}_j) \qquad (8.9a)$$

†† The angular frequency of an electromagnetic wave is denoted by ν, while the angular frequency of a phonon is ω. The use of ν as an angular frequency is not the usual practice, but it has been used in one standard treatment (H3).

§§ The permeability is assumed to be unity (A1, p. 188). F is the electric field strength.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and κ is the wave vector (ν/c) of the exciting light. The total effect is a sum of (8.9) over all the upper states. In this approximation (8.9) is just $N|\langle\varphi'|\mathbf{r}|\varphi\rangle|^2$, as one would expect.

The second perturbation produces changes in (8.6) and (8.7). We first apply the trap-trap interaction and then use (8.8). Since $\Phi_0(g)$ is nondegenerate, its energy level will be slightly shifted. The perturbation, however, will affect $\Phi_0(u,k)$ more profoundly. It removes some or all of the degeneracy and the upper level will fan out (Fig. 5). The various eigenfunctions are denoted by $\Phi_1(u,k)$. One may no longer replace $\mathbf{R}_{\text{eff}}$ by $\mathbf{r}$, since the phase factor is of utmost importance; hence, the matrix element becomes

$$\langle\Phi_1(u,k)|\mathbf{R}_{\text{eff}}|\Phi_1(g)\rangle. \tag{8.10}$$

Many of the cross terms in the square of the matrix cancel due to the random distribution of the $\mathbf{R}_{\text{eff}}$. The old theory of spectroscopic stability (V1, p. 137) gives some useful information. It can be applied directly to (8.10) to show that

$$\sum_k^N |\langle\Phi_0(u,k)|\mathbf{R}_{\text{eff}}|\Phi_0(g)\rangle|^2 = N|\langle\varphi'|\mathbf{r}|\varphi\rangle|^2$$

$$= \sum_k^N |\langle\Phi_1(u,k)|\mathbf{R}_{\text{eff}}|\Phi_1(g)\rangle|^2. \tag{8.11}$$

The perturbation is assumed to be small enough that the $\Phi_1(u,k)$'s can be expanded in terms of the $\Phi_0(u,k)$'s.

The next step is to define $g(\nu)$ by the relation

$$\sum_{\nu-\frac{1}{2}\Delta\nu}^{\nu+\frac{1}{2}\Delta\nu} |\langle\Phi_1(u,k)|\mathbf{R}_{\text{eff}}|\Phi_1(g)\rangle|^2$$

$$= Ng(\nu)|\langle\varphi'|\mathbf{r}|\varphi\rangle|^2\Delta\nu. \tag{8.12}$$

The summation is restricted to states where the energy difference lies between $\hbar\nu\pm\frac{1}{2}\hbar\Delta\nu$. The left-hand expression is simply the sum over all the possible transitions, while the right-hand side defines $g(\nu)$. The theorem of spectroscopic stability assures that $\int_0^\infty g d\nu = 1$ as required by (8.5).

The development is quite formal and gives no information regarding the shape and width of g. These are the required steps, however, to introduce the factor properly into the theory of optical absorption. It shows that the upper level widens.

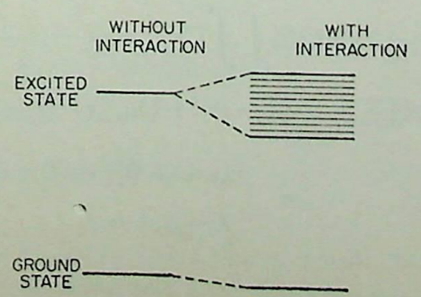

FIG. 5. Schematic diagram showing the effect of the interaction between centers.

This development indicates why one would not expect sharp lines in the absorption spectra of solids, except when one "imperfection" is very well shielded from another. Hence the absence of sharp lines in the spectroscopy of solids is to be expected (see the edge emission of CdS. K2a, p. 117). This factor also accounts for the fact that the F center absorption does not have a fine structure. Unfortunately, we are unable to estimate the width of g, or to separate this broadening from the one caused by dispersion (K5).

It is assumed that g is wider than $\hbar\omega$, where ω is an effective phonon angular frequency. The g function is next replaced by the Dirac δ function. To obtain the moments, we integrate over many such functions. For the shape calculation, more care has to be used. On introducing the δ function into (8.3) and recalling items (1a) and (1b), we obtain

$$s(\nu) = b(4\pi^2/3)(e^2/\hbar c)\nu|\{\langle\Psi'(A)|\mathbf{r}|\Psi(A)\rangle\}|^2 \times\delta\{\nu-(1/\hbar)(E'-E)\}I_\nu. \tag{8.13}$$

The dimensions of s_{atomic} and $s(\nu)$ are not the same. s_{atomic} has the dimensions of ml^2t^{-3} (m for mass, l for length, and t for time). This arises because I_ν has the dimension of mt^{-2}, not energy per l^2t. Equation (8.3) assumes implicitly a δ function (S2, p. 215). In (8.13) we have written the δ function explicitly; hence $s(\nu)$ has the dimensions of ml^2t^{-2}.

The absorption cross section per imperfection in cm^2 is defined by

$$\frac{\text{energy absorbed per unit time in interval } \Delta\nu}{\text{energy falling on imperfection per unit time for unit area in interval } \Delta\nu}$$

or

$$\sigma(\nu) = b(4\pi^2/3)(\nu e^2/\hbar c)|\{\langle\Psi'(A)|\mathbf{r}|\Psi(A)\rangle\}|^2 \times\delta\{\nu-(1/\hbar)(E'-E)\}. \tag{8.13a}$$

This cross section must be summed over all the point imperfections in unit volume. Before summing (8.13a) we must consider the probability of finding a given imperfection with energy E. This is given by (B, p. 178)

$$P(v_t) = \Pi^i p(v_j), \tag{8.14}$$

where

$$p(v_j) = e^{-v_j\beta}(1-e^{-\beta_j}) = 2e^{-(v_j+\frac{1}{2})\beta_j}\sinh\tfrac{1}{2}\beta_j \tag{8.14a}$$

and

$$\beta_j = \hbar\omega_j(g)/k\theta. \tag{8.14b}$$

The time average absorption constant is $\sum_{v,v'}P(v_t)\cdot\sigma(\nu)$. To obtain the actual measured absorption coefficient, the δ function must be eliminated. This can be done by the integration

$$\alpha_\omega = \frac{1}{\omega}N\int_{\nu-\frac{1}{2}\omega}^{\nu+\frac{1}{2}\omega}\sum_{v,v'}P(v_t)\sigma(x)dx. \tag{8.15}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

On averaging $\sigma(\nu)$, the error of replacing $\hat{g}$ by δ is eliminated. For the calculation of the moments, one need not use (8.15) but simply integrate $\sum_{v,v'} P(v_t)\sigma(\nu)$ over many narrow "lines."

To carry the solution further, the delta functions must be expressed in terms of integrals. ν appears in the δ function and as a multiplier of this function. If the oscillator strength‖ ‖ is introduced (S4),

$$f(\mathbf{R}) = (2/3)(m/\hbar)\nu |\langle \varphi'(\mathbf{R}) | \mathbf{r} | \varphi(\mathbf{R}) \rangle|^2. \quad (8.16)$$

α_ω takes the following form

$$\alpha_\omega(\nu) = \frac{1}{\omega} bN \int_{\nu-\frac{1}{2}\omega}^{\nu+\frac{1}{2}\omega} d\nu \left[\frac{2e^2\pi^2}{cm} \sum_{v,v'} P(v_t) |\{\chi'|f^{\frac{1}{2}}|\chi\}|^2 \times \delta\left\{ \nu - \frac{1}{\hbar}(E'-E) \right\} \right], \quad (8.17)$$

which nicely hides the frequency dependence of the term in front of the δ function. The mass of the electron (m) is introduced by using (8.16). It can be considered as an adjustable parameter provided we have a knowledge regarding the behavior of f. The next step is to forget about f's dependence on ν and $\mathbf{R}$ and write¶¶

$$\alpha_\omega(\nu) = \frac{2\pi^2 be^2}{c\omega m} fN \int_{\nu-\frac{1}{2}\omega}^{\nu+\frac{1}{2}\omega} G(x)dx \quad (8.18)$$

$$G_n(\nu) = \sum_{v,v'} P(v) |\{\chi'|\chi\}|^2 \delta\{\nu - (1/\hbar)(E'-E)\}. \quad (8.18a)$$

In Sec. 10 we shall show that G_n is normalized. In (8.18) the shape and moments only depend on the χ's. The assumption that f is independent of $\mathbf{R}$ is known as the Condon approximation. Meyer has eliminated this restriction. There is no good theoretical justification for the steps taken in obtaining (8.18). The frequency spread may be large over the bands, and one can hardly replace ν by an "average" value. In emission, a ν^3 appears before the δ function, and it certainly cannot be ignored. For instance, from the data on the emission from the F center in KCl at 77°K (D3) we know that $\epsilon_r(em) = 1.08$ ev and $\epsilon_v(em) = 1.35$ ev. Since $(1.25)^3 = 2$, the frequency factor could lead to an experimentally detectable skewness. One can assume that f is a function of the q's and of ν and still solve the moments problem. The present absorption data are not good enough to justify these added complications; they are considered only in Appendix V.

The theoretical problem is to know whether to treat $|\langle \varphi'(\mathbf{R}) | \mathbf{r} | \varphi(\mathbf{R}) \rangle|$ or $|\langle \varphi'(\mathbf{R}) | \mathbf{p}_j(e) | \varphi(\mathbf{R}) \rangle|$ as the fundamental quantity independent of the frequency. The sum rules are in terms of the f (S4, p. 503). Dirac's formulation of the radiation problem deals with matrix elements of $\mathbf{p}_j(e)$, while the elementary theory uses the matrix elements of the electron displacement. To refine the theory, this problem must first be resolved. This has not be done so far.

One cannot simply borrow theorems which hold for atoms since the phonon modes give additional degrees of freedom to the problem and their effects on the sum rules have to be explored with care.

Peierls, many years ago (S2, p. 671), considered the absorption problem when the centers have a lattice geometry. In this case the $\Phi_1(u,k)$'s have a rather simple form and strict selection rules exist for the transitions. The problem here has only an indirect relation to the one considered by Peierls. We assume a random distribution of imperfections; hence, no strict selection rules.

Lax and Burstein (L2a) have formulated the above in an alternate manner. They consider H_1 as a perturbation which broadens the Ψ's making bands out of the ground and excited states. This is an interesting and useful point of view.

Although there are limitations on (8.18a) we shall now use it to obtain the absorption coefficient when the ϵ_{jj}'s equal zero (Sec. 9), and the distribution moments in the most general case (Sec. 10). The foregoing equations apply rigorously to all the models discussed in the general introduction.

9. SHAPE OF THE BAND

Using a development of O'Rourke and Pekar, the integral $G_n(\nu)$ can be evaluated giving expressions for α. The problem, however, has to be simplified by the use of two assumptions: (1) that $\epsilon_{jj} = 0$, and (2) that an effective mean frequency exists. Use is made of Mehler's formula and various expansions of the modified Bessel function.

The delta function can be expressed in the integral form (H3, p. 66)

$$\delta(\nu) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\nu t} dt. \quad (9.1)$$

By substituting (8.14a) and (9.1) into (8.18a), one obtains

$$G_n(\nu) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i(\nu-\nu_{ug})t} \Pi^j F_j(t) dt, \quad (9.2)$$

where

$$F_j = 2 \sinh \tfrac{1}{2}\beta_j \int\int [\textstyle\sum_{v_j} \exp[-(v_j+\frac{1}{2})\lambda_j] \chi_j(q_j)\chi_j(q_j')] \times [\textstyle\sum_{v_j'} \exp[-(v_j'+\frac{1}{2})\mu_j] \chi_j'(Q_j)\chi_j'(Q_j')] dq_j dq_j' \quad (9.3)$$

$$\nu_{ug} = (1/\hbar)[\epsilon_u(\theta) - \epsilon_g(\theta)] \quad (9.3a)$$

$$\lambda_j = \beta_j + i\omega_j t \quad (9.3b)$$

and

$$\mu_j = -i\omega_j t. \quad (9.3c)$$

‖ ‖ $\langle \varphi' | \mathbf{r} | \varphi \rangle$ is assumed to be real; thus $f^{\frac{1}{2}}$ is real. This allows a simplification in the notation without any limitation on the derived equations.

¶¶ Since the absorption is small, we may assume that n is independent of ν (B5).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

To obtain (9.3) we have employed (3.9), (3.24), (8.1a), and (8.2a). Also, a term has been added and subtracted in the exponent to make the next step simpler. μ_j arises from (9.1), while λ_j is a result of a combination of (9.1) and (8.14a). Finer mathematical points, such as the use of (9.1) and the rearrangement of the order of the summation will not be considered.

O'Rourke now uses Mehler's formula which can be written

$$\sum_{v_j} e^{-(v_j+\frac{1}{2})\xi}\chi_j(q_j)\chi_j(q_j') = \alpha_j(2\pi\sinh\xi)^{-\frac{1}{2}}\exp\{-\tfrac{1}{4}\alpha_j^2[(q_j+q_j')^2\tanh\tfrac{1}{2}\xi + (q_j-q_j')^2\coth\tfrac{1}{2}\xi]\}, \quad (9.4)$$

where

$$\alpha_j^2=\omega_j/\hbar \quad (9.4a)$$

(Appendix III). The substitution of (9.4) into (9.3) makes the integrand take the simple form, $\exp[-ax^2+b]$. The operation can now be carried out by the use of standard formula, giving

$$F_j=\exp\left\{\frac{-\epsilon_j^2}{\omega_j^2(\omega_j\hbar)[\coth(\frac{1}{2}\beta_j+\frac{1}{2}i\omega_j t)-\coth\frac{1}{2}i\omega_j t]}\right\}$$

$$=\exp\left\{-\left(\frac{\epsilon_j^2}{2\omega_j^3\hbar}\right)[\coth\tfrac{1}{2}\beta_j - i\sin\omega_j t - \coth\tfrac{1}{2}\beta_j\cos\omega_j t]\right\}. \quad (9.5)$$

The steps between (9.3) and (9.5) are essentially elementary, although slightly involved. The use of Mehler's formula does not require that the frequency of the two states be equal. One may obtain more general expressions for the F_j's [Vasileff (V1), or Dexter (D1)]. We want to obtain $\alpha_\omega(\nu)$, hence must obtain a rather simple expression for $\Pi_j F_j$. This is the reason for requiring that all the ϵ_{jj} vanish.

Now

$$\Pi^j F_j=\exp\left\{\sum_j -\tfrac{1}{2}\left(\frac{\epsilon_j^2}{\hbar\omega_j^3}\right)\times(\coth\tfrac{1}{2}\beta_j - i\sin\omega_j t-\coth\tfrac{1}{2}\beta_j\cos\omega_j t)\right\}. \quad (9.6)$$

The existence of the following equality (for any θ and t) must be assumed

$$\sum_j\left(\frac{\frac{1}{2}\epsilon_j^2}{\hbar\omega_j^3}\right)[\coth\tfrac{1}{2}\beta_j - i\sin\omega_j t-\coth\tfrac{1}{2}\beta_j\cos\omega_j t] = [\coth\tfrac{1}{2}\beta - i\sin\omega t-\coth\tfrac{1}{2}\beta\cos\omega t]\sum_j\frac{\frac{1}{2}\epsilon_j^2}{\hbar\omega_j^3}. \quad (9.7)$$

The relation certainly holds for the CC and Fröhlich's model. If the local modes cluster about a point between the acoustical and optical branches, (9.7) should be a good approximation. One would not expect (9.7) to hold if the important modes are a combination of several types (longitudinal optical and local) involving radically different frequencies. Combined with (8.14b), it defines the "effective" or "average" frequency ω. In Sec. 11 a method is described which can be used to determine whether or not several effective frequencies exist. For the time being, (9.7) is used. Introducing the famous Huang and Rhys factor, we write

$$G_n(\nu)=\frac{1}{2\pi}\int_{-\infty}^{\infty}dt\,e^{-i(\nu-\nu_{u0})t}\times\exp\{-S[\coth\tfrac{1}{2}\beta - i\sin\omega t-\coth\tfrac{1}{2}\beta\cos\omega t]\}, \quad (9.8)$$

where

$$S=\tfrac{1}{2}\sum_j\frac{\epsilon_j^2}{\omega_j^3\hbar}=\sum_j\frac{1}{\omega_j\hbar}\tfrac{1}{2}\omega_j^2(Q_j-q_j)^2, \quad (9.8a)$$

S is nondimensional. Equation (9.8) resembles integrals which appear in the definition of Bessel's function. To relate G_n to these functions, the following transformation is introduced:

$$\eta=(1/2)i\beta. \quad (9.9)$$

The integration variable of (9.8) is now changed to

$$x=\omega t-\eta. \quad (9.10)$$

Since one may show, with the use of (9.9) and (9.10) that

$$i\sin\omega t+\coth\tfrac{1}{2}\beta\cos\omega t=\operatorname{csch}\tfrac{1}{2}\beta\cos x, \quad (9.11)$$

Eq. (9.8) takes the form***

$$G_n(\nu)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{dx}{\omega}\exp\{-i(p\eta+px) - S\coth\tfrac{1}{2}\beta+S\operatorname{csch}\tfrac{1}{2}\beta\cos x\}, \quad (9.12)$$

where

$$p=(\nu-\nu_{u0})/\omega. \quad (9.13)$$

One may show that†††

$$\frac{1}{2\pi}\int_{-\infty}^{\infty}\exp\{y\cos\xi-ip\xi\}d\xi=\sum_{-\infty}^{\infty}\delta(p-k)I_p(y), \quad (9.13a)$$

where I_p is the modified Bessel function and k is an integer. Now (9.12) takes the form

$$G_n(\nu)=\frac{e^{-ip\eta-S\coth\frac{1}{2}\beta}}{\omega}\sum_{-\infty}^{\infty}\delta(k-p)I_p[S\operatorname{csch}\tfrac{1}{2}\beta]. \quad (9.14)$$

*** In (9.12) an alternate path of integration is used. This can be justified by taking contour integrals and assuming that p is an integer.

††† To establish (9.13) one must use an integral expression for I_n (J1, p. 547), and it is noted that $\delta(x)=\sum_{-\infty}^{\infty}e^{2\pi inx}$ for $-\frac{1}{2}<x<\frac{1}{2}$, etc.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Equation (9.14) requires that p or $(1/\omega)\sum_j \omega_j(v_j'-v_j)$ be an integer for any value of v_j and v_j'. This means that $\omega=\omega_j$. Evidently Eq. (9.7), which holds for any t, can only be satisfied under this condition. Therefore, the derivation holds exclusively for this condition.

The author believes that this is the result of using the δ function in Eq. (8.13) and that in reality Eq. (9.14) will give the correct shape (envelope—see Fig. 4) even if the frequencies vary over a small range. We thus write

$$p=v_t'-v_t. \tag{9.15}$$

Equation (9.14) can be put in the alternate form

$$G_n(\nu)=\left[\frac{\bar{v}+1}{\bar{v}}\right]^{p/2}\frac{1}{\omega}\exp[-S(2\bar{v}+1)] \times\sum_k\delta(k-p)I_p\{2S[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}\}, \tag{9.16}$$

where $\bar{v}=\frac{1}{2}[\coth(\beta/2)-1]$, the mean quantum number of a normal mode in the ground state.

The actually observed shape is obtained from (8.18); hence,

$$\frac{1}{\omega}\int_{\nu-\frac{1}{2}\omega}^{\nu+\frac{1}{2}\omega}G_n(\nu)d\nu=\frac{1}{\omega}\left[\frac{\bar{v}+1}{\bar{v}}\right]^{p/2} \times\exp[-S(2\bar{v}+1)]I_p\{2S[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}\}, \tag{9.17}$$

where p is the integer closest to $(1/\omega)(\nu-\nu_{u0})$. ω appears in (9.17) because the unknown g function has been effectively replaced by the step function.

$$g=0 \quad \text{for} \quad \nu<\frac{1}{\hbar}(E'-E)-\tfrac{1}{2}\omega$$

$$g=\frac{1}{\omega} \quad \text{for} \quad \frac{1}{\hbar}(E'-E)-\tfrac{1}{2}\omega\leq\nu\leq\frac{1}{\hbar}(E'-E)+\tfrac{1}{2}\omega \tag{9.18}$$

$$g=0 \quad \text{for} \quad \frac{1}{\hbar}(E'-E)+\tfrac{1}{2}\omega<\nu.$$

The factor $1/\omega\exp[-S(2\bar{v}+1)]$ does not affect the frequency dependence of the absorption, i.e., the shape. It is convenient to introduce an average shape factor

$$G_A=\left[\frac{\bar{v}+1}{\bar{v}}\right]^{p/2}I_p\{2S[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}\}. \tag{9.19}$$

The term $1/\omega$ is a measure of the width of the band. Larger ω's cause wider absorption bands provided that the ϵ_j's remain the same. We shall see that $\int_{-\infty}^{\infty}e^{-S(2\bar{v}+1)}G_A dp=1$ so that $\int G_n(\nu)d\nu=1$ (Appendix IV and Sec. 10).

Equation (9.19) is exact for the models considered provided (9.7) applies. It does not require that $\epsilon_j\to 0$. This is not obvious unless the derivation of O'Rourke is used. Two alternate forms of G_A will now be found using some developments originally due to Pekar (P1).

(a) Low Temperature

If $\theta\to 0$, $\bar{v}$ is a small quantity. It is useful to define $z=2S[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}$ which is also a small quantity. Here $v_t\to 0$, and $p>0$; hence, our concern is for the situation where p is a positive integer. Now we expand I_p as follows (J1, p. 542):

$$I_p(z)=\frac{(\frac{1}{2}z)^p}{p!}\left[1+\frac{(\frac{1}{2}z)^2}{p+1}+\frac{(\frac{1}{2}z)^4}{2(p+2)(p+1)}+\cdots\right] \tag{9.20}$$

and obtain

$$G_A(\nu)\approx G_l(\nu)=S^p/p!. \tag{9.21}$$

This approximation improves as p increases. For large S, one may use the Stirling approximation and show that the maximum occurs at

$$p_l=S. \tag{9.22}$$

This corresponds to the angular frequency

$$\nu_l=\nu_{u0}+S\omega. \tag{9.22a}$$

Since p is an integer, S in (9.22) refers to the nearest integer value. The violet side of the band corresponds to higher values of p, where (9.21) is a better approximation.

It seems appropriate to refer to (9.21) by the name Pekarian, since Pekar was the first to employ expansion (9.20) in relation to this problem. The use of Eq. (9.21) requires the inequality,

$$z^2/4p\ll 1. \quad \text{(Pekarian Criterion)} \tag{9.23}$$

At the point of maximum absorption this is equivalent to the conditions

$$S\bar{v}\ll 1. \tag{9.24}$$

The shape of the absorption band of some F centers seems to be given by (9.21) (K4). Little is known about this type of curve. Its behavior is studied in Appendix IV.

(b) High Temperature

At high temperatures $\bar{v}$ is not small and $z\gg 1$. As the temperature increases, z approaches the value $2Sk\theta/\hbar\omega$. This suggests the use of the asymptotic expansion‡‡‡

$$I_p(z)=\frac{e^z}{(2\pi z)^{\frac{1}{2}}}\left\{1+\sum_{n=1}^{\infty}\frac{(-1)^n[4p^2-1][4p^2-3^2]\cdots[4p^2-(2n-1)^2]}{n!(8z)^n}\right\}. \tag{9.25}$$

‡‡‡ This type of expansion is discussed by Jeffreys and Jeffreys (J1). Their equation for I_p, however, is slightly in error.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Our interests are not limited to small values of p or to the first few terms of the sum. p may have the value of 100; hence, for appropriate values of z the major contribution arises from terms with high values of n. If the series can be broken off before $r \approx p$, the simple form is obtained,

$$I_p(z) = \frac{e^z}{(2\pi z)^{\frac{1}{2}}}\left\{1 - \frac{p^2}{2z} + \frac{1}{2!}\left(\frac{p^2}{2z}\right)^2 - \frac{1}{3!}\left(\frac{p^2}{2z}\right)^3 + \cdots\right\}$$

$$= \frac{1}{(2\pi z)^{\frac{1}{2}}} \exp\left(z - \frac{p^2}{2z}\right). \tag{9.26}$$

For (9.26) to hold, one requires that $(2n-1)^2 \ll 4p^2$ for all important terms. This will be true if $p^2/2z < 1$. When $p^2/2z > 1$, the expansion (9.26) must be explored further. The highest terms of the series occur (approximately) at $n = p^2/2z$, or Eq. (9.26) requires that $4p^2 > (p^4/z^2)$. These facts suggest that criteria for the applicability of (9.26) are

$$|2z/p| > 1 \tag{9.27a}$$

and (Gaussian criteria)

$$|p| \gg 1. \tag{9.27b}$$

The high-temperature shape is obtained by substituting (9.26) in (9.19),

$$G_A(\nu) \approx G_h(\nu)$$

$$= \frac{1}{(2\pi z)^{\frac{1}{2}}} \exp\left\{z - \frac{1}{2z}p^2 + \frac{p}{2}\ln\left(1 + \frac{1}{\bar{v}}\right)\right\}. \tag{9.28}$$

Its maximum occurs at

$$p_h = \tfrac{1}{2}z \ln\left(1 + \frac{1}{\bar{v}}\right) = \frac{\hbar\omega}{2k\theta}z \tag{9.29}$$

$$\approx S \tag{9.29a}$$

and

$$\nu_h = \nu_{u0} + (\hbar\omega^2/2k\theta)z \tag{9.30}$$

$$\approx \nu_{u0} + S\omega. \tag{9.30a}$$

The peak value of G_h is

$$G_h(\max) = \frac{1}{(2\pi z)^{\frac{1}{2}}} \exp\left\{z\left(1 + \frac{\hbar^2\omega^2}{8k^2\theta^2}\right)\right\}. \tag{9.31}$$

Hence

$$G_h = G_h(\max) \exp\left\{-\frac{1}{2}\left(\frac{p}{\sqrt{z}} - \frac{\hbar\omega}{2k\theta}\sqrt{z}\right)^2\right\} \tag{9.32}$$

$$= G_h(\max) \exp\left\{-\frac{1}{2z\omega^2}(\nu - \nu_h)^2\right\}. \tag{9.32a}$$

Thus at high temperatures the absorption should be Gaussian provided (9.27a) and (9.27b) apply.

TABLE III.

θ °K	$\bar{v}$	$\frac{4k\theta}{\hbar\omega}$	$\frac{[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}}{\theta}$	z for $S=30$
5	3.11×10^{-13}	0.139	1.11×10^{-7}	3.34×10^{-5}
10	5.58×10^{-7}	0.278	7.47×10^{-5}	4.48×10^{-2}
20	7.47×10^{-4}	0.555	1.36×10^{-3}	1.63
30	8.30×10^{-3}	0.834	3.04×10^{-3}	5.47
50	5.95×10^{-2}	1.39	5.02×10^{-3}	15.1
75	0.172	2.08	5.96×10^{-3}	26.8
100	0.311	2.78	6.40×10^{-3}	38.4
200	0.949	5.56	6.80×10^{-3}	81.6
400	2.31	11.1	6.91×10^{-3}	165.
600	3.69	16.7	6.93×10^{-3}	250.
800	5.07	22.2	6.96×10^{-3}	334.

If the ϵ_j's do not approach zero, p will be greater than unity, and criterion (9.27b) will hold, except in the region where $p=0$, i.e., $\nu = \nu_{u0}$. Since $p_h > 0$, this occurs to the red of the peak. In the broad bands which arise in polar solids, this will not be a real limitation on the applicability of (9.32a).

To test criterion (9.27a) at the peak, it is combined with (9.29) to give

$$2z/p_h = 4k\theta/\hbar\omega > 1. \tag{9.33}$$

In Table III some typical values of $\bar{v}$, z, $(4k\theta/\hbar\omega)$ and $(1/\theta)[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}$ are given. The phonon frequency selected was $2\pi(3\times10^{12})$ sec^{-1} (M5). The table indicates that (9.33) applies above room temperature. Since $p < p_h$ for the red side of the band, Eq. (9.23a) should hold there.

If we multiply G_h by $(1/\omega)\exp\{-S(2\bar{v}+1)\}$ one sees that $\int G_n d\nu = 1$, provided one neglects small quantities. In the next section we show that this relation holds exactly.

Deviation from a Gaussian form should be looked for on the violet side of the peak where $p > p_h$; here (9.27b) could break down. This treatment does not suggest that a band should be Gaussian for all ν, although at medium temperatures one would suspect that the red side would approach such a shape. At some temperatures the following conditions may occur: $(2z/p) > 1$ for the red side (Gaussian), and $(z^2/4p) < 1$ on the violet side (Pekarian).

We may obtain an expression for H at high temperatures. Equations (7.7) and (9.32a) show that $2\hbar^2\omega^2 z = 1/a^2$ and

$$H = (5.545)^{\frac{1}{2}}\hbar\omega z^{\frac{1}{2}}$$

$$= (5.545)^{\frac{1}{2}}S^{\frac{1}{2}}\hbar\omega \operatorname{csch}^{\frac{1}{2}}\tfrac{1}{2}\beta. \tag{9.34}$$

For high θ

$$H = (11.090Sk\hbar\omega)^{\frac{1}{2}}\theta^{\frac{1}{2}}. \tag{9.34a}$$

Equation (9.30) predicts that the peak of the absorption band is temperature dependent. The dependence is given by $\nu_{u0}(\theta)$ and z/θ. In Table III the dependence of $[\bar{v}(\bar{v}+1)]^{\frac{1}{2}}/\theta$ on θ is given. This quantity is proportional to z/θ of (9.30). Except at low temperatures, where our approximations break down, this term is insensitive to variations of θ.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

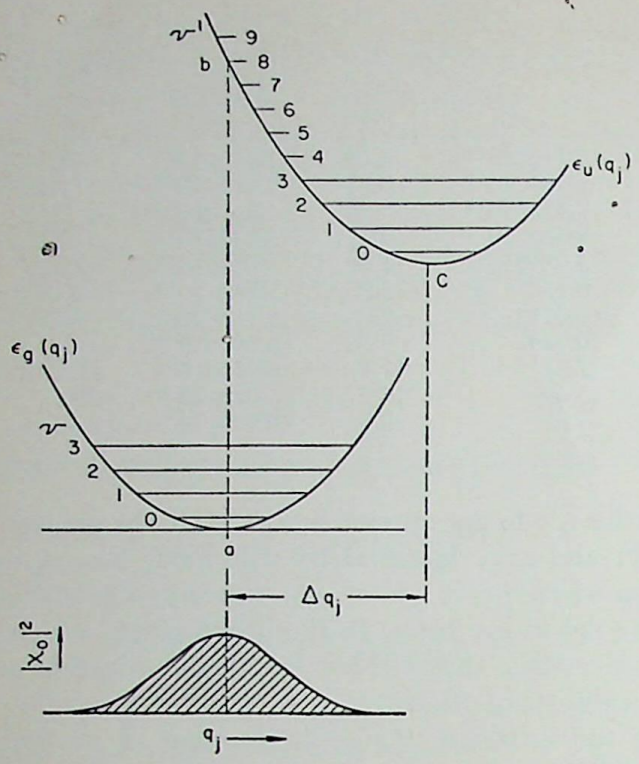

FIG. 6. Diagram illustrating the broadening effect. The upper and lower configurational coordinates are shown. The distribution probability at 0°K is given in the lower left corner. Point "a" is at $\epsilon_g(\mathbf{R}_g)$, while "c" is at $\epsilon_u(\mathbf{R}_u)$.

The dependence of ν_h and H on temperature given by (9.30) and (9.34) is due to the approximations used in this section. These relations require correction, but the high-temperature prediction is valid and (9.34a) holds.

The physical interpretation of the above equations is indicated in Fig. 6. Although the development considers more than one mode, this description is limited to the CC model. This is done for convenience only, as the arguments can be generalized to any number of effective modes. Since the ϵ_{jj}'s are zero, the frequencies are not affected by the transition. In Fig. 6 $\epsilon_g(q)$ and $\epsilon_u(q)$ are plotted against q. The horizontal lines are various values of $E=\epsilon_g+\hbar\omega(v+\frac{1}{2})$ and $E'=\epsilon_u+\hbar\omega(v'+\frac{1}{2})$. The relative probability of finding a particular value of q, when the electron is in the ground state, is shown by the shaded area on the lower left. The probable distribution, $\rho(q)$, at absolute zero is $\chi^2(q)$ for $v=0$. At any finite temperature it is

$$\rho(q)=\sum_v p(v)\chi^2(q)=\frac{1}{a\sqrt{\pi}}\exp[-q^2/a^2], \qquad (9.35)$$

where

$$a=\left(\frac{\hbar}{\omega}\right)^{\frac{1}{2}}\coth^{\frac{1}{2}}\tfrac{1}{2}\beta. \qquad (9.35a)$$

One obtains (9.35) from (8.14a) and (9.4). At high temperatures a^2 has the value $2k\theta/\omega^2$, and (9.35) has a form which one can obtain by Boltzmann's statistics if the total energy of the system is assumed to be $(1/2)\omega^2q^2$. The actual energy of the system, however, is not $(1/2)\omega^2q^2$, since (9.35) is the sum over many states unless $\theta=0$°K.

The first question is: what is S? It is simply the ratio of the difference in potential energy at 0 (b) and at Δq (c) to the energy of a phonon, $\hbar\omega$ (Fig. 2). This follows from (3.24) and (9.8a). The maximum of the absorption occurs for transitions from $v=0$ to $v'=S$, as is seen with the use of (9.22) and (9.29a). This is the vertical transition if we ignore the zero-point energy. One would expect this to be the peak because of the shape of $\rho(q)$. So far complex analysis has not led to anything very surprising.

The bandshape at low temperature, however, is non-Gaussian; indeed it is nonsymmetric. This means that $|\{\chi_{S+1}'|\chi_0\}|^2$ does not equal $|\{\chi_{S-1}'|\chi_0\}|^2$. Here 0 and $S\pm1$ refer to the quantum states of χ and χ'. This lack of symmetry leads to the skewness in absorption curves at low temperatures. This has created a serious problem in the experimental analysis (K2a, p. 119). We stress that this lack of symmetry stems from the properties of the χ's and not $\epsilon_u(q)-\epsilon_g(q)$, which for this problem has the simplest form possible, namely

$$\hbar\nu=\hbar\nu_{ug}+\tfrac{1}{2}\omega^2(\Delta q)^2-\omega^2(\Delta q)q. \qquad (9.36)$$

ν is a *linear* function of q.

At high temperatures the spread on the red side occurs because of transitions where $v_t'-v_t$ is smaller than S. The violet side is affected by transitions from the ground state where v_t' is greater than S. The theory suggests that these transitions tend to make the curve more symmetrical and in the extreme case, Gaussian.

The Williams' approximation suggests that the transition probability at frequency ν is obtained from (9.35) and (9.36). First, (9.36) is solved for q; then the absorption is obtained from $\rho(q)$. Since $\rho(q)$, however, is composed of several states (unless $\theta=0$°K), this approach is inconsistent, since $\epsilon_u(q)-\epsilon_g(q)$ does not equal $E'-E$. Further, the matrix elements are somewhat asymmetrical.

The question of the asymmetry of the absorption band is an extremely fundamental one. The Williams' approximation happens to give the correct temperature dependence of H (Sec. 10). Equation (9.34) might also be a good approximation. Actually, it is a poor one. It is the asymmetry of the curves, i.e., Eq. (9.21), which gives us the necessary insight to understand what is really happening.

In conclusion, one should mention that Krivoglaz and Pekar (K5) report a shape where the term const$(\nu-\nu_h)^3$ is added to the expression in the curly brackets of Eq. (9.32a). This term will create a skewness when $(\nu-\nu_h)$ is not too small. As ν approaches ν_h, the curve becomes symmetric and almost Gaussian. This fits the experimental data better than (9.32a), since there is another adjustable parameter. The experimental data seems to resemble a double Gaussian curve more nearly, however. There is no evidence, however, to believe that a discontinuity in the absorption occurs at $\nu=\nu_h$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Arguments by Kubo and Toyozawa (K6) indicate that the simple model employed here gives a symmetrical shape at high temperatures. This same conclusion can be obtained from the higher moments calculated by O'Rourke. The conclusion of Sec. 9(b) regarding the symmetry of the shape is not due to (9.25). Experimental data suggests (K4) that the results may not be completely valid. However, the simplifying assumptions give some useful information regarding the low-temperature shape and the transition probabilities.

10. METHOD OF MOMENTS

The method of moments was developed by Lax (L1) and extended by Meyer (M8). We now combine the development of Part I with this powerful approach.

Returning to Eq. (8.13a), we first sum over v_t' and then take a weighted average over v_t using (8.14); thus,

$$\alpha(\nu)=\frac{K}{2\pi}\,\mathrm{Av}\int_{-\infty}^{\infty}\sum_{v'}dt\{\chi|f^{\frac{1}{2}}|\chi'\}\{\chi'|f^{\frac{1}{2}}|\chi\}$$

$$\times\exp\left\{i\left[(E'-E)\frac{1}{\hbar}-\nu\right]t\right\}, \quad (10.1)$$

$$K=2\pi^2be^2N/cm. \quad (10.1a)$$

In this approach $\alpha(\nu)$ is used. To obtain (10.1) we have made use of (9.1). Av implies a weighted average over the ground vibrational states. By expanding $\exp\{iE't/\hbar\}$ in series, one may show that

$$\chi'\exp\{iE't/\hbar\}=e^{iH_ut/\hbar}\chi'. \quad (10.2)$$

Now (10.1) takes the form

$$\alpha(\nu)=\frac{K}{2\pi}\,\mathrm{Av}\int dt\sum_{v'}$$

$$\times\{\chi|f^{\frac{1}{2}}e^{iH_ut/\hbar}|\chi'\}\{\chi'|f^{\frac{1}{2}}e^{-iH_gt/\hbar}|\chi\}e^{-i\nu t}. \quad (10.3)$$

We note that E' depends on v_t'; H_u, however, does not. Therefore, we take it out of the sum. Equation (10.3) is a product of the three integrals: one over t; the other over the nuclear coordinates involved in the first { }; while the third arises because of the second { }. Since the χ's form a complete set in q space, we use the following property of eigenfunctions (H3, p. 66)

$$\sum_{v_j'}\chi_j'(q_j)\chi_j'(q_j')=\delta(q_j-q_j') \quad (10.4)$$

and write

$$\alpha(\nu)=\frac{K}{2\pi}\int dt\,\mathrm{Av}\{\chi|f^{\frac{1}{2}}e^{iH_ut/\hbar}f^{\frac{1}{2}}e^{-iH_gt/\hbar}|\chi\}e^{-i\nu t}. \quad (10.5)$$

Now the Condon approximation is used to remove f from the matrix element, giving

$$\alpha(\nu)=\frac{Kf}{2\pi}\,\mathrm{Av}\int dt\{\chi|e^{i(H_u-H_g)t/\hbar}|\chi\}e^{-i\nu t}. \quad (10.6)$$

The quantum mechanics is contained in the order of the operators; thus one cannot remove $\exp\{i(H_u-H_g)t/\hbar\}$ from the matrix (Appendix V).

By assuming that f is frequency independent, we see that α is the Fourier transform of the function $Kf\,\mathrm{Av}\{\chi|\exp[i(H_u-H_g)t/\hbar]|\chi\}$ and it follows that (M7, p. 252)

$$Kf\,\mathrm{Av}\{\chi|e^{i(H_u-H_g)t/\hbar}|\chi\}=\int\alpha(\nu)e^{i\nu t}d\nu. \quad (10.7)$$

Setting $t=0$, we find

$$\int\alpha(\nu)d\nu=Kf. \quad (10.8)$$

Therefore, it follows that $G_n(\nu)$ of (8.18a) is normalized. The thermal vibration spreads the absorption band but does not affect the area. Equation (10.8) is based on the approximation that f is *independent* of frequency. Had we assumed that $\langle\varphi'|\,\mathbf{r}\,|\varphi\rangle$ is frequency dependent, the zero moment would be temperature sensitive. Using (7.1), it follows that

$$M_0=\hbar Kf. \quad (10.9)$$

Further,

$$\left\{(\hbar/i)(\partial/\partial t)\int\alpha(\nu)e^{i\nu t}d(\hbar\nu)\right\}_{t=0}=\int\alpha(\nu)\hbar\nu d(\hbar\nu)$$

$$=(\hbar^2/i)Kf\,\mathrm{Av}[(\partial/\partial t)\{\chi|e^{i(H_u-H_g)t/\hbar}|\chi\}]_{t=0} \quad (10.10)$$

and

$$M_1=\hbar Kf\,\mathrm{Av}\{\chi|H_u-H_g|\chi\}. \quad (10.10a)$$

Now,

$$\left\{-\hbar^2\frac{\partial^2}{\partial t^2}\int\alpha(\nu)e^{i\nu t}d(\hbar\nu)\right\}_{t=0}=\int(\hbar\nu)^2\alpha(\nu)d(\hbar\nu) \quad (10.11)$$

and

$$M_2=\hbar Kf\,\mathrm{Av}\{\chi|(H_u-H_g)^2|\chi\}. \quad (10.14)$$

By similar methods we may evaluate the higher moments. For these situations, one may not write

$$\exp\{(i/\hbar)(H_u-H_g)t\}$$

for

$$\exp\{(i/\hbar)H_ut\}\exp\{(-i/\hbar)H_gt\}$$

as explained in Appendix V.

To evaluate (10.10) and (10.12), expressions for the operator H_u-H_g as well as $\mathrm{Av}\{\chi|q_j^n|\chi\}$ (n is an integer) are required. The matrix elements can be

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

calculated from the properties of the χ's and are (I, p. 173–181)

$$\mathrm{Av}\{\chi|q_j|\chi\}=0 \tag{10.13a}$$

$$\mathrm{Av}\{\chi|q_j^2|\chi\}=[\hbar/2\omega_j(g)]\coth\tfrac{1}{2}\beta_j \tag{10.13b}$$

$$\mathrm{Av}\{\chi|q_j^3|\chi\}=0 \tag{10.13c}$$

$$\mathrm{Av}\{\chi|q_j^4|\chi\}=3[\hbar/2\omega_j(g)]^2\coth^2\tfrac{1}{2}\beta_j. \tag{10.13d}$$

β_j is defined by (8.14b) where the ground state ω_j is used.

An expression for (H_u-H_g) is obtained from (8.1), (8.2) and the expansion technique employed in Sec. 3. It now follows that

$$H_u-H_g=\Delta\epsilon(\theta)+\textstyle\sum_j \epsilon_j q_j+\frac{1}{2}\sum_j \epsilon_{jj}q_j^2 +\frac{1}{2}\sum_{jk}{}' \epsilon_{jk}q_jq_k \tag{10.14}$$

$$\Delta\epsilon(\theta)=\epsilon_u(\mathbf{R}_g)-\epsilon_g(\mathbf{R}_g)=\hbar\nu_{ug}+\tfrac{1}{2}\textstyle\sum_j \epsilon_j^2/\omega_j^2(u). \tag{10.14a}$$

To obtain (10.14) and (10.14a) use has been made of (3.27). When comparing Secs. 9 and 10, it should be remembered that $\Delta\epsilon$ does *not* equal $\hbar\nu_{ug}$. The prime on the sum means that $j\neq k$. The temperature dependence of $\Delta\epsilon$ is due to the expansion of the crystal. We assume that the ϵ_j's and ϵ_{jk}'s are independent of θ. The derivatives are evaluated at the equilibrium position of the ground state, and the q_j's are the normal modes for this state.

The evaluation of M_1 and M_2 is now straightforward. Using (10.9) and (10.10)

$$\bar{\epsilon}=(M_1/M_0) =\Delta\epsilon(\theta)+\tfrac{1}{4}\textstyle\sum_j \epsilon_{jj}[\hbar/\omega_j(g)]\coth\tfrac{1}{2}\beta_j. \tag{10.15}$$

To evaluate M_2 we square (10.14), i.e.,

$$\begin{aligned}(H_u-H_g)^2=&\Delta\epsilon^2(\theta)+\textstyle\sum_j \epsilon_j^2q_j^2+\sum_{jk}{}' \epsilon_j\epsilon_k q_jq_k\\ &+\tfrac{1}{4}\textstyle\sum_j \epsilon_{jj}^2q_j^4+\tfrac{1}{4}\sum_{jk}{}' \epsilon_{jj}\epsilon_{kk}q_j^2q_k^2\\ &+2\Delta\epsilon(\theta)\textstyle\sum_j \epsilon_jq_j+\Delta\epsilon(\theta)\sum_j\epsilon_{jj}q_j^2\\ &+\Delta\epsilon(\theta)\textstyle\sum_{jk}{}' \epsilon_{jk}q_jq_k\\ &+\sum_{jk}\epsilon_j\epsilon_{kk}q_jq_k^2,\end{aligned} \tag{10.16}$$

where again terms involving $\epsilon_j\epsilon_{kl}$ and $\epsilon_{ij}\epsilon_k\epsilon_l$ $(k\neq l)$ have been omitted. Using (10.12) and (10.13) results in

$$\begin{aligned}(M_2/M_0)=&\Delta\epsilon^2(\theta)+\textstyle\sum_j[\hbar/2\omega_j(g)]\epsilon_j^2\coth\tfrac{1}{2}\beta_j\\ &+\tfrac{1}{8}\textstyle\sum_j\epsilon_{jj}^2[\hbar^2/\omega_j^2(g)]\coth^2\tfrac{1}{2}\beta_j\\ &+\tfrac{1}{16}\textstyle\sum_{jk}\epsilon_{jj}\epsilon_{kk}[\hbar^2/\omega_j(g)\omega_k(g)]\coth\tfrac{1}{2}\beta_j\coth\tfrac{1}{2}\beta_k\\ &+\tfrac{1}{2}\Delta\epsilon(\theta)\textstyle\sum_j\epsilon_{jj}[\hbar/\omega_j(g)]\coth\tfrac{1}{2}\beta_j.\end{aligned} \tag{10.17}$$

A combination of (7.3), (10.15), and (10.17) gives the important equation

$$\begin{aligned}m^2=&\textstyle\sum_j\epsilon_j^2[\hbar/2\omega_j(g)]\coth\tfrac{1}{2}\beta_j\\ &+\tfrac{1}{8}\textstyle\sum_j\epsilon_{jj}^2[\hbar^2/\omega_j^2(g)]\coth^2\tfrac{1}{2}\beta_j.\end{aligned} \tag{10.18}$$

We have made only two assumptions—that f is not a function of ν or q, and that the adiabatic approximation can be used to terms of ϵ_{ij}, ϵ_{kl}, and $\epsilon_j\epsilon_{kl}$, where $k\neq l$.§§§ These equations are extremely general. The possibility of calculating the q's and ϵ's about a point imperfection with any degree of accuracy is small. Hence, the equations as they stand are of little use. We must make further assumptions to obtain relations between $\bar{\epsilon}$, m, and θ which involve parameters to be evaluated experimentally. The generality of the equations assures one that terms will not be omitted. Thus, we may apply the equations to the Huang-Rhys problem (the Fröhlich approximation) and compare our results with those of O'Rourke and Meyer. On the other hand, we may make the approximation used by Klick.

(a) CC Model

Here, there is only one q whose ground state has the angular frequency $\omega(g)$; hence, from Sec. 3,

$$X=q/M^{\frac{1}{2}}, \tag{10.19}$$

where M is an effective mass of the order of an ionic mass. For this model

$$\begin{aligned}\Delta\epsilon(q)=&\hbar\nu_{ug}+\tfrac{1}{2}\omega^2(u)(q-\Delta q)^2-\tfrac{1}{2}\omega^2(g)q^2\\ =&\hbar\nu_{ug}+\tfrac{1}{2}\omega^2(u)(\Delta q)^2-\omega^2(u)(\Delta q)q\\ &+\tfrac{1}{2}[\omega^2(u)-\omega^2(g)]q^2.\end{aligned} \tag{10.20}$$

Using the definition of (3.18),

$$\epsilon_j=-\omega^2(u)\Delta q=-\omega^2(u)M^{\frac{1}{2}}\Delta X \tag{10.21a}$$

and

$$\epsilon_{jj}=\omega^2(u)-\omega^2(g)\approx 2\omega(g)\Delta\omega. \tag{10.21b}$$

Equations (10.15) and (10.18) now have the form

$$\bar{\epsilon}=\Delta\epsilon(\theta)+\tfrac{1}{2}\hbar\Delta\omega\coth\tfrac{1}{2}\beta \tag{10.22a}$$

and

$$m^2=\left\{\frac{1}{2}\frac{\omega^2(u)}{\hbar\omega(g)}M(\Delta X)^2\right\}\hbar^2\omega^2(u)\coth\tfrac{1}{2}\beta \times+\tfrac{1}{2}\hbar^2(\Delta\omega)^2\coth^2\tfrac{1}{2}\beta. \tag{10.22b}$$

A generalized S is defined by the use of (10.18) and (10.22b),

$$S=\frac{1}{2\hbar}\sum_j\epsilon_j^2\frac{1}{\omega_j(g)\omega_j^2(u)}=\tfrac{1}{2}\sum_j\frac{\omega_j^2(u)}{\hbar\omega_j(g)}(Q_j-q_j)^2. \tag{10.23}$$

The last step uses (3.24). S equals the expression in the curly brackets of (10.22b). This definition agrees with (9.8a) and is equivalent to the one used by Meyer. An exact comparison is somewhat involved since Meyer takes a thermal average over modes which do not include V_I and V_e of (5.2). The S for absorption and emission need not be the same. Both $\omega(g)$ and $\omega(u)$ enter into the definition.

§§§ We also assume that the modes are nondegenerate (Sec. 3).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The second term in (10.22b) is new; it arises from a superior approximation.‖‖‖ To estimate its effect we set $\theta=0°\text{K}$ and $\Delta\omega\approx\omega$. Now

$$m_0=\hbar\omega[S+(1/2)]^{\frac{1}{2}}$$
$$=\hbar\omega S^{\frac{1}{2}}[1+(1/4S)]. \quad (10.22c)$$

If S is of the order of 30, the correction term is of the order of 0.01, which is at the experimental limit of accuracy. If S were smaller than 30, and if $\Delta\omega$ is large, one might be able to detect the second term in (10.22b). This would be done from the temperature behavior of m.

Equation (10.22a) has a great deal less information than (10.22b), since no reliable information regarding $\Delta\epsilon(\theta)$ exists. As stated, $\Delta\epsilon$ may change because of the lattice expansion. ϵ_m for the F center seems to be a function of the interionic distance, d. From empirical data, one may obtain the following relation, $\epsilon_m(d)=\text{const}\ d^{-1.84}$ (Mollwo (M10), Ivey (I1)). Combining this with density measurements at various temperatures, one may calculate $\Delta\epsilon(\theta)$. Using Henglein's (H3a) expansion data for KCl, one obtains

$$\epsilon_m(193°\text{K})-\epsilon_m(273°\text{K})=0.011\ \text{ev}$$
$$\epsilon_m(80°\text{K})-\epsilon_m(273°\text{K})=0.025\ \text{ev},$$

where $\bar{\epsilon}$ has been replaced by ϵ_m. This change of ϵ_m is too small to explain the observed temperature variation (0.040 ev and 0.070 ev), which is an indication that $\Delta\omega\neq0$ for this particular absorption band. One might attempt to combine the Ivey relation with (10.22a).

On the other hand, we may assume that $\Delta\epsilon(\theta)$ equals a constant. This can be tested by plotting ϵ_m against $\coth\beta/2$; β having been evaluated empirically from (10.22b). If the data give the equation $A+B\coth\beta/2$, one may evaluate $\Delta\epsilon$ and $\Delta\omega$. There is a danger in this procedure since $\Delta\epsilon(\theta)$ may also vary as $A+B\coth\beta/2$ over a limited range of temperatures [for small β, $\coth\beta/2\approx(2/\beta)$]. In this situation the coefficient of $\coth\beta/2$ would not equal $\frac{1}{2}\hbar\Delta\omega$. As the range of θ increases, the possibility of accidental correlation decreases.

Using recent data on the F center in KCl, ω has been evaluated with the use of (10.22b) (without the second term). From (10.22a) ω, $\bar{\epsilon}$, and $\hbar\Delta\omega$ were determined. One again concludes that the correction to (10.22b) is very small.

Klick and Schulman (K2a, p. 110) have used the Williams' approximation to obtain an expression for H. It is identical to the first term of (10.22b), provided H and m are proportional. This does not imply that the derivation given here is identical to the one obtained previously. The latter method does not give the second term of Eq. (10.22b), nor the Pekarian shape (at low temperature). The latter is readily observable and requires understanding. If one uses Eq. (9.34), H depends on the $\text{csch}\beta/2$ instead of $\coth\beta/2$, which indicates that the relation given by William and Hebb (W3) and by Lax (L2) is fortuitous.

‖‖‖ A term of this nature appears in the formal treatment of Kubo and Toyozawa (K6).

(b) Huang-Rhys Problem

In this case we assume that all the modes have a single frequency given by the LST relation; then

$$\bar{\epsilon}=\Delta\epsilon(\theta)+\tfrac{1}{2}\textstyle\sum_j\hbar\Delta\omega_j\coth\frac{1}{2}\beta \quad (10.24a)$$

and

$$m^2=\hbar^2\omega^2(u)S\coth\tfrac{1}{2}\beta+\tfrac{1}{2}(\textstyle\sum_j\hbar^2\Delta\omega_j^2)\coth^2\tfrac{1}{2}\beta. \quad (10.24b)$$

Equation (10.24a) was first obtained by O'Rourke, using the approximation that $\Delta\omega$ is *very* small. Later Meyer obtained this equation by an alternate method. These authors did not note the thermal dependence of $\Delta\epsilon(\theta)$. The first term of Eq. (10.24b) has been given before, while the second term is new, see however (K6). It may be detected when careful measurements are made on bands with small S's.

(c) Double-Frequency Model

We may apply (10.15) and (10.18) to more complex situations. An alternate model is one with two effective ground frequencies ω_1 and ω_2. For this situation

$$\bar{\epsilon}=\Delta\epsilon(\theta)+\frac{\hbar}{4\omega_1(g)}\{\textstyle\sum_j\epsilon_{jj}\}\coth\frac{1}{2}\beta_1$$
$$+\frac{\hbar}{4\omega_2(g)}\{\textstyle\sum_i\epsilon_{ii}\}\coth\frac{1}{2}\beta_2 \quad (10.25a)$$

and

$$m^2=\hbar^2\omega_1^2(u)S_1\coth\tfrac{1}{2}\beta_1+\hbar^2\omega_2^2(u)S_2\coth\tfrac{1}{2}\beta_2. \quad (10.25b)$$

Here

$$S_1=\tfrac{1}{2}\textstyle\sum_j[1/\hbar\omega_j(g)\omega_j^2(u)]\epsilon_j^2 \quad (10.26a)$$

$$S_2=\tfrac{1}{2}\textstyle\sum_i[1/\hbar\omega_i(g)\omega_i^2(u)]\epsilon_i^2 \quad (10.26b)$$

$$\beta_1=(\hbar/k\theta)\omega_1(g)\quad\text{and}\quad\beta_2=(\hbar/k\theta)\omega_2(g). \quad (10.26c)$$

j is summed over the modes associated with the frequency ω_1, and i is over the ω_2 modes. The second term in (10.18) is omitted.

We again use an effective frequency and write

$$S_1=[1/2\hbar\omega_1(g)\omega_1^2(u)]\textstyle\sum_j\epsilon_j^2. \quad (10.27)$$

Since the data are always limited to a range in temperature, this may be less restrictive than (9.7) which must hold for every value of t. If (10.27) is to hold for every value of β_j, there cannot be a spread in the values of the ω's.

We may assume that S_1 is related to the local modes, and S_2 is associated with the longitudinal optical modes. β_1 will be roughly half β_2. The question is: can one detect the difference between (10.25a and b) and (10.22a and b) or (10.24a and b)? For the answer to this question, we must consider the various methods employed to analyze the data.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

11. ANALYSIS OF EXPERIMENTAL DATA

In the last two sections, we derived several equations which can be compared with experimental data. Various attempts have been made to analyze the data with radically different results. Some of the difficulties stem from the data itself, yet this is not the major problem. While at low temperatures (Table I) there is considerable disagreement, this is not the case at room temperature (Table IV). The agreement between Mollwo's (M10) and the most recent data (M5) is good. Russell and Klick's (R1) value of H seems to be too large at all temperatures.

Russell and Klick conclude that (10.22b) (without the second term) applies to the F center, provided the angular frequency in KCl is 1.6×10^{13} sec^{-1}. On the other hand, Pekar (P2 and 4) and Meyer (M8 and 9) conclude that the same equation holds, provided a value of 3.95×10^{13} sec^{-1} is used. It was obtained from the LST relation. Pekar and Meyer use Mollwo's data. The reason for the difference stems from the method of treating the data. One may use Mollwo's data with an alternate method of analysis and obtain 2×10^{13} sec^{-1} for ω.

Pekar's analysis is most remarkable (P4, p. 129 ff and p. 145 ff). He had only one adjustable constant, the

TABLE IV. F center in KCl at room temperature.

Experimenter	(M10)	(R1)	(M5)
ϵ_m ev	2.20	2.2	2.225
H ev	0.35	0.39	0.35

effective mass of the electron. It was evaluated from the experimental ϵ_m at room temperature; hence, his results should apply to the most recent data. Using this value, Pekar calculated S by employing (9.8a) and (3.18a). For the relation between the q's and the X's he used the very long wave approximation (B, p. 213). His value of S for KCl is 23.8. Using this value, the LST relation (10.24b), and (7.7b), we compute the values in Table V. Equation (7.7b) was used to relate m and H; this gives

$$H^2=8\ln 2(\hbar\omega)^2\coth\tfrac{1}{2}(\hbar\omega/k\theta). \tag{11.1}$$

The calculation of H at 300°K does not agree with the value, 0.40, reported in Pekar's paper of 1950 since it was based on Eq. (9.34), not (10.24b). Strangely enough, in 1953 Krivoglaz and Pekar (K5) derived (11.1). However the corrected numerical values of H were not reported in Pekar's subsequent review paper (P3), although (11.1) was quoted. The correct expression for H at 0°K seems to have been first given by Pekar in 1950 (P1). While the results of the table are not satisfactory, they are really quite remarkable, since there is only *one* adjustable parameter.

A method of analysis which the author believes is quite useful is now discussed. If one has to use Eqs. (10.15) and (10.18) with various values of β_j, the problem becomes hopeless since the number of adjustable parameters is too large. The opposite point of view, which is very naive, is that one exists and that Eqs. (10.22a) and (10.22b) or (10.24a) and (10.24b) apply. If we further assume that $\Delta\epsilon$ is independent of temperature, there are only four adjustable parameters and the equations of interest take the forms¶¶¶

$$\bar{\epsilon}=\Delta\epsilon+B\coth\tfrac{1}{2}(\hbar\omega/k\theta) \tag{11.2}$$

$$m^2=\hbar^2\omega^2S\coth\tfrac{1}{2}(\hbar\omega/k\theta)+\tfrac{1}{2}B^2\coth^2\tfrac{1}{2}(\hbar\omega/k\theta). \tag{11.3}$$

Next we may assume that B^2 is very small compared to $\hbar^2\omega^2S$ and hence can be omitted from (11.3). This is true for the F center in KCl. To obtain m from an arbitrary curve is a laborious process involving a great deal of numerical work. In some cases, one may be able to replace m by H [Eqs. (7.7b) and (7.12b)], hence in the simplest situation we wish to test critically the relation

$$H^2=H^2(0)\coth\tfrac{1}{2}(\hbar\omega/k\theta), \tag{11.4}$$

where $H(0)$ is the half-width at 0°K. It can readily be obtained from measurements at low temperatures (approx 4°K). The validity of (11.4) is based on the assumption that the ratio of m to H is temperature independent. This has to be tested by numerical integration.

Equation (11.4) suggests plotting $\coth^{-1}[H/H(0)]^2$ against $1/\theta$. We have the desired test if $1/\theta$ can be varied over a large range of values. A straight line going through the origin is a clear indication of the validity of (11.4) and the development in Sec. 10. Further, it shows that there is one effective mode, so the theory developed in Sec. 9 can be used. Such a plot is a more critical test of the theory than the previous methods of analysis, since one deals with straight lines rather than a complex curve. If one combines this technique of analysis with Mollwo's data, one obtains the 2×10^{13} sec^{-1} value mentioned above.

Three alternate methods have been suggested.

(1) Klick (K2) plots H against $\theta^{\frac{1}{2}}$. At high temperatures, a straight line is obtained whose slope is proportional to $S^{\frac{1}{2}}\omega^{\frac{1}{2}}$. At moderately low temperatures, a departure from a straight line is obtained and the analysis requires the determination of this departure. At extremely low temperatures (about 25°K), one gets a straight horizontal line. While Klick's approach is useful, one cannot determine the validity of (11.4) in a

TABLE V. Comparison of Pekar's parameters with experiment.

θ	H (cal)	H (exp)
300°K	0.43	0.35
0°K	0.30	0.16

¶¶¶ We assume here that $(\Sigma_j\hbar\Delta\omega_j)^2=\Sigma_j(\hbar\Delta\omega_j)^2$ which, of course, need not be true except in the CC model. The B from (11.2) will however give us the order of magnitude of B^2 in (11.3).

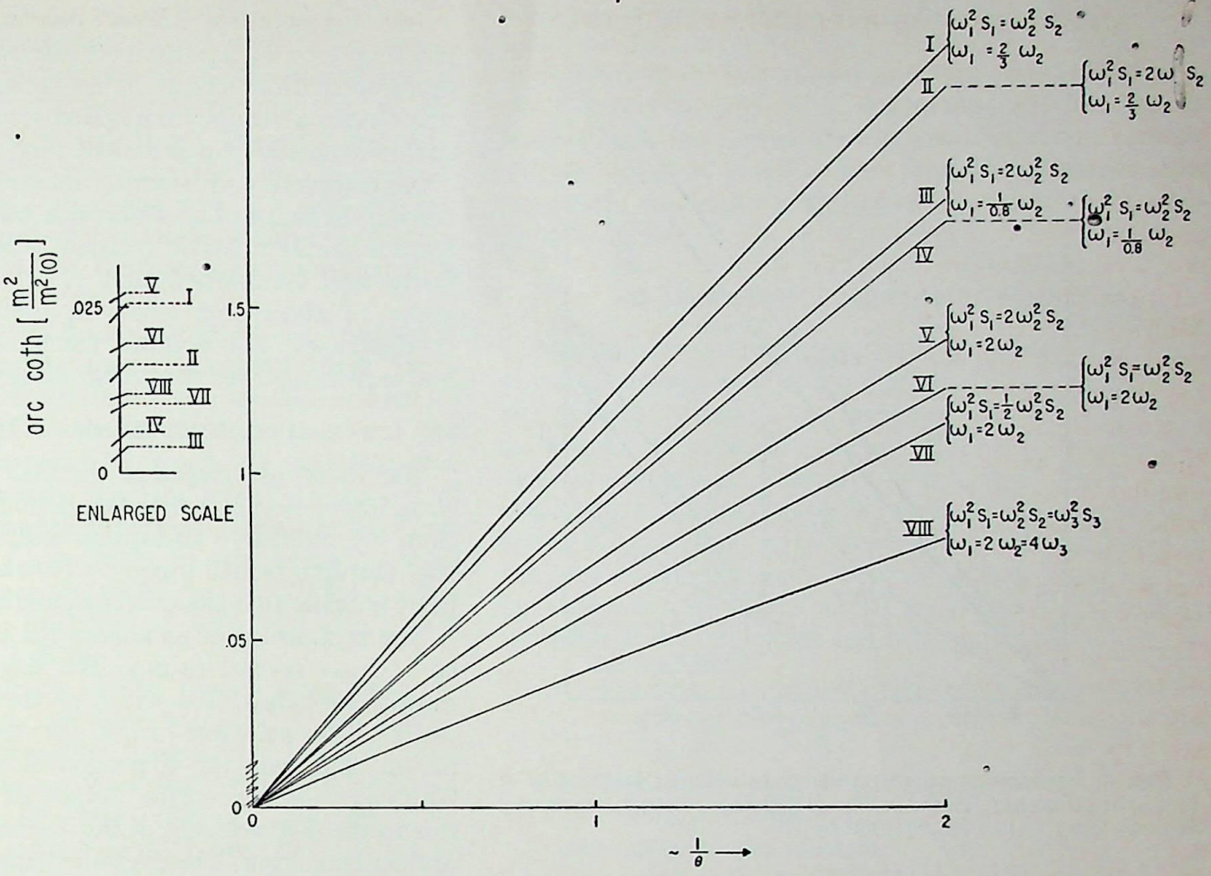

FIG. 7. Broadening caused by more than one effective frequency. Note the curve at $1/\theta=0$. In some cases m can be replaced by H. Analysis of more than one ω.

critical manner since the points are not supposed to lie on a straight line.

(2) Pekar (P3) has plotted H against θ. In this case one does not get a straight line except at extremely low temperatures. An analysis of experimental data by this method is difficult, and the author knows of no detailed study using this approach.

(3) Meyer (M8) has plotted $(H/\hbar\omega)^2$ against $\coth\frac{1}{2}(\hbar\omega/k\theta)$ using a known ω (from the LST relation). An erroneous ω can be detected only at low temperatures (under 100°K). If a great many points are available below 100°K, one can see that his technique does not give a straight line except for the correct value of ω. Thus, using recent data on the F center in KCl (M5) one may show that his ω is incorrect. Mollwo's data had too few points in the critical region, so that Meyer was unable to detect the deviation. Actually, Meyer was unable to confirm (11.4) and was forced to add a constant [Appendix V and Eq. (11.5)].

We are particularly interested in what happens when there is a breakdown in the approximation made in arriving at (11.4). In particular, how does Eq. (10.25b) look on a plot of $\coth^{-1}[H^2/H^2(0)]$ against $1/\theta$? This question is only meaningful provided the ratio of ω_1 to ω_2 is not near unity, and S_1 and S_2 are approximately equal. One cannot hope to detect the difference between Eqs. (10.25b) and (11.4) with the use of experimental data unless there is an appreciable contribution from both types of modes, and the frequencies are distinct. One may assume that both the local modes and the longitudinal optical modes interact with the trapped electron. The local modes should be in the gap between the acoustical and optical branches. In NaCl and KCl this gap is roughly at one-half the frequency of the longest longitudinal optical modes; hence the ratio of the ω's should be of the order of 2.

To understand the problem various $\coth^{-1}[H(\theta)/H(0)]^2$ against $1/\theta$ plots have been made using several ratios of S_1 to S_2 and several ratios of ω_1 to ω_2 (Fig. 7).**** In making these graphs, the values of S_1, S_2, ω_1, and ω_2 were assumed to be known. Then, $H^2(\theta)$ was calculated. From this H^2, $\coth^{-1}[H^2(\theta)/H^2(0)]$ was computed. Since the data refer only to a limited range of temperatures, the curvature shown in Fig. 7 will not be detected. A sure indication of the difference between (11.4) and (10.25b) is in the intercept, where $1/\theta=0$. If the line goes through the origin, we have a fair experimental proof that (11.4) applies, and that there is a *single effective* frequency. If not, one must attempt to express H by means of a more complete equation. Strangely enough, the data on the F center in KCl can be interpreted in this very simple manner (K4).

Similarly, in Fig. 8 plots have been made with the use of Meyer's equation, namely,

$$H^2=C+D\coth\tfrac{1}{2}(\hbar\omega/k\theta). \qquad (11.5)$$

This equation assumes that $f^{\frac{1}{2}}$ is a linear function of q

**** In Figs. 7 and 8 we assume that $m\approx H$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

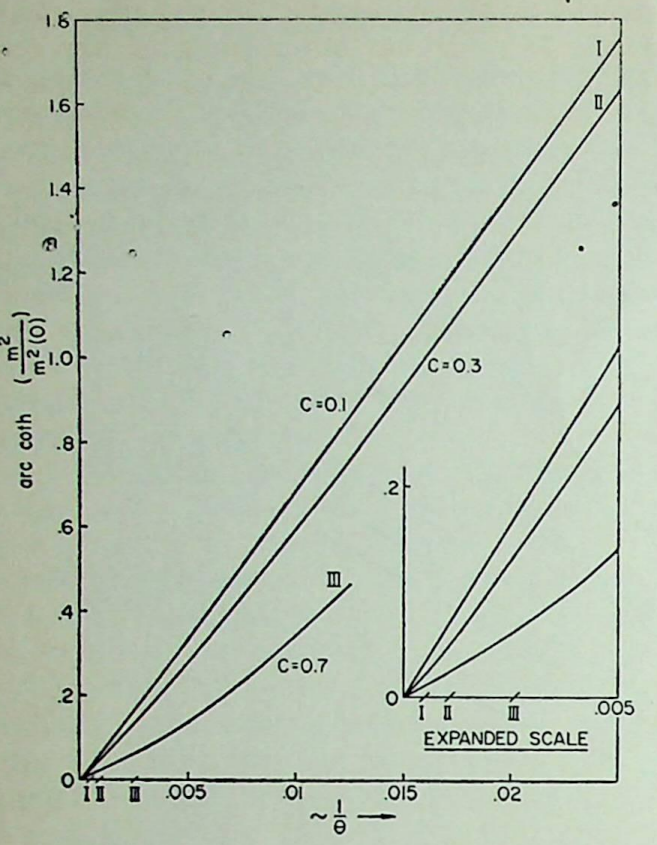

FIG. 8. Broadening effects when f^2 is a linear function of q. Note the curve at $1/\theta=0$ [in Eq. (11.5) D is set equal to unity]. In some cases m can be replaced by H.

(Appendix V). Again, the same conclusion is obtained; namely, the validity of (11.5) can be judged by the interception at $1/\theta=0$.

Use of this kind of plot requires measurements at both low and high temperatures. Measurements at extremely low temperatures cannot be used, since $H^2/H^2(0)$ approaches unity, and there is a large uncertainty in the $\coth^{-1}$ of $H^2/H^2(0)$ due to slight uncertainty in the evaluation of H^2 (one or two parts per thousand). This is one disadvantage of this plot. The other proposed methods are no better in this temperature region if (11.4) applies.

As suggested by Meyer, one may test (11.2) by plotting $\bar{\epsilon}$ or ϵ_m against $\coth\frac{1}{2}(\hbar\omega/k\theta)$, ω having been determined from (11.4). If $\Delta\epsilon$ is independent of θ one will obtain a straight line. Of course, $\Delta\epsilon$ could vary as const$+b\coth\beta/2$ for a limited range of θ.

No completely satisfactory method suggests itself for testing the shape of an absorption band, since we do not have a simple analytic relation between α and ϵ. It is fairly well established that (7.7) and (7.8) will not apply to absorption bands in solids, except in very special cases. For detailed comparison of the theory and experiment, see the forthcoming paper (K4).

12. CONCLUSIONS OF PART II

The theory developed in the first sections is applied to an impurity center with two bound states. Considerations are limited to absorption and, for a large part, to the simplest model (Secs. 9, 11, and 17). It has thus been possible to make exact calculations.

The broadening of an absorption band is on account of at least several causes. The band is composed of narrow subbands. The width of these arises from the uncertainty principle, from the center-center interaction, and from the dispersion of the normal modes. The envelope curve (the height of the subbands) is due to the displacement of the normal modes during an optical transition. The over-all shape arises from terms which appear in phonondynamics and are absent in electrodynamics. The broadening effects are illustrated in Fig. 9. The energy levels of the system are drawn on the left-hand side. At absolute zero before the transition, the system is in its ground state ($v_t=0$). Various transition probabilities exist for the excitation to levels in the excited state ($v_t'=0, 1, 2, \cdots$). The height of the vertical lines on the right are proportional to these transition probabilities (Eq. 9.21). The result is an asymmetric curve which resembles the F center in KCl (K4). We have plotted v_t' from right to left as is usually done. For emission one may exchange v_t and

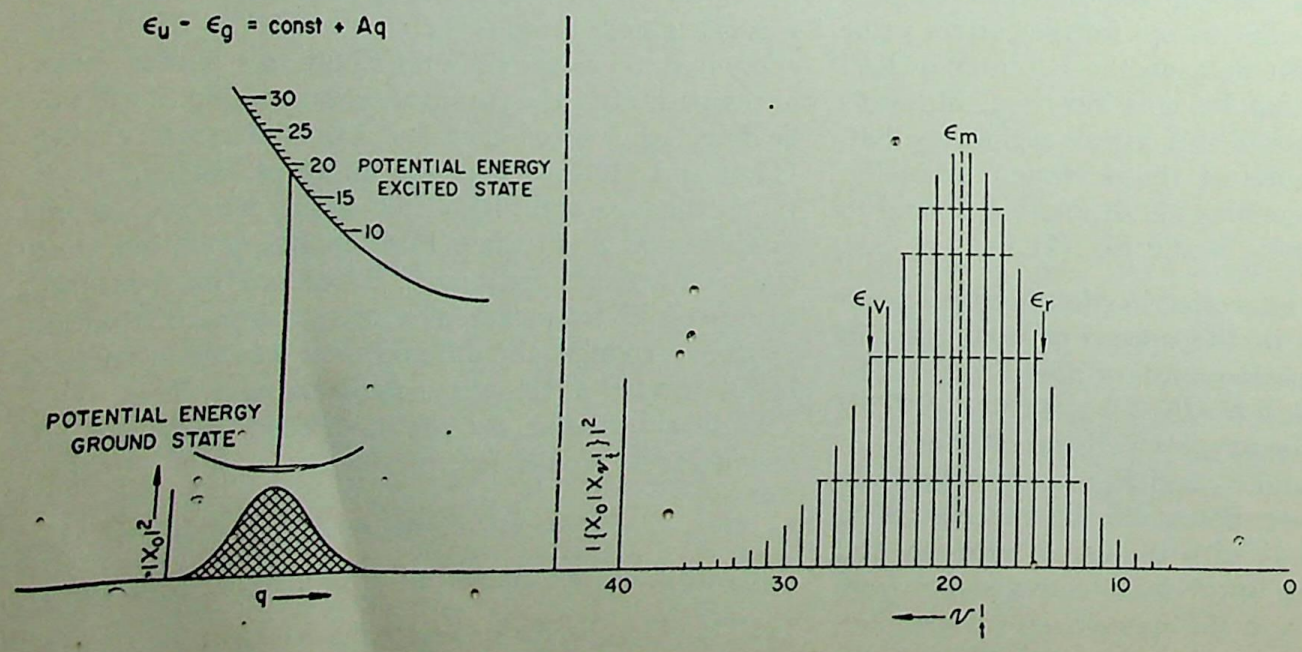

FIG. 9. Band shape at $\theta=0°$K for $S=20$. The vertical lines on the right are proportional to the transition probability. Note $\epsilon_v-\epsilon_m>\epsilon_m-\epsilon_r$ and the lack of symmetry for all values of α.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

v_t'. Here the emitted energy is $\Delta\epsilon(Q=0)-\hbar\omega(v_t-v_t')$, and the diagram should be "flipped over." The absorption curve shown on the right is probably not limited to the model on the left but only requires that all the important normal modes (whose ϵ_j do not equal zero) have an effective single frequency (Sec. 9). The generalization of Fig. 9 to any model with a single effective frequency is a result of the use of Mehler's formula. This is a result of the fundamental contribution of O'Rourke.

The shape presented is thus exact for the model considered at absolute zero. To extend these calculations to higher temperatures, various approximations must be made. The asymmetry disappears and the agreement with experiment is much less good. One may indeed show rigorously that the model on the left of Fig. 9 gives a symmetrical curve at high temperatures. This can be done most simply by calculating the third moment (01). Hence the model has to be expanded to predict the shape observed at high temperatures in the F center of KCl (K4).

As to the accuracy of the theory developed, the simple model (Sec. 9) does not predict the correct relation between E^e and E^a. For example, in the F center of KCl, $S=30$, $\hbar\omega=0.012$ ev, and E^a (at 0°K) $=2.3$ ev. From (4.2a), $E^e=E^a-2\hbar\omega S=1.6$ ev compared to the experimental value of 1.2 ev (V1). For this situation we may not let the frequency change be zero, and a more complex calculation is required (Sec. 10). For large values of S, we do not have to describe the potential curve over the entire range if we are interested only in emission or in absorption shapes. Returning to Fig. 2, the absorption shape is determined primarily by the potential curves about points "a" and "b." Likewise the emission shape also is determined primarily from the curves about "c" and "d." Therefore, one would expect that the general features given in Sec. 9 will be observed. While the general features are given by the development, the calculations are not truly exact. The change in the frequency and higher-order terms must have a detectable influence. These corrections must somehow be used to explain the asymmetry at high temperatures. How to do this remains an unsolved problem.

In Secs. 10 and 18 several more general models are considered where various corrections are introduced in the expression for the moments. The effects on $\bar{\epsilon}$ and m^2 are, however, small and usually beyond the range of detection, except for the case where we have two radically different frequencies. We thus conclude that the basic equations have considerable validity. This field needs more reliable data and its complete analysis in terms of absorption and emission. In Sec. 11 some methods of analysis are suggested.

ACKNOWLEDGMENTS

Professor F. Seitz is thanked for suggesting that this review be written and for several helpful discussions. The assistance of Dr. A. Ellett in writing the manuscript is acknowledged. Further, the author is grateful to J. D. Konitzer for carrying out a detailed experimental investigation of the shape and thermal behavior of the F center in KCl. The author also thanks Mrs. B. Heckenbach for typing the manuscript.

Note added in proof.—Some interesting recent data have been reported by K. Maeda, J. Phys. Soc. Japan 14, 478 (1959).

13. APPENDIX I. LIST OF SYMBOLS

Although an attempt was made to associate a single physical concept with every symbol, this has not always been possible; thus, ϵ has been used for an eigenvalue as well as for a photon energy. Similarly, m has two distinct meanings. Usually subscripts have been employed to differentiate between physical concepts, or the symbols have been employed at distinct parts of the text. Gaussian units have been employed except for experimental values which are reported in electron volts. Only the important symbols are listed here.

a_s—Smakula's constant—ratio of the area under an absorption curve to the product of $\alpha_m H$; also $(G_m H)^{-1}$
b—local field correction (Sec. 8)
c—velocity of light
e—charge on the electron
f—oscillator strength (8.16)
g—shape factor associated with items (a) and (b) of Sec. 7, as well as the dispersion of the modes
$\hbar$—Planck constant divided by 2π
h_e—electronic Hamiltonian (3.3)
h_v—vibration Hamiltonian (3.4)
k—Boltzmann constant
(k)—the kth nuclei
m—See (7.3) except (8.16)
q_j—reduced coordinate of the jth normal mode (In Part II it is associated with the ground state.)
Δq_j—shift in the equilibrium position $q_j'-Q_j$ (3.24)
p—see (9.13)
p_t—see (9.22)
p_h—see (9.29)
p_j—momentum operator associated with q_j
$\mathbf{r}$—coordinate of all the electrons of interest to the problem
t—kinetic energy operator associated with the excess electron
v_j—vibration quantum number associated with the jth mode, v_j (ground), and v_j' (upper)
v_t—total vibrational quantum number, i.e., $\sum_j v_j$
$\bar{v}$—thermal average quantum number of single mode
B—reference (B2)
E—total energy in vibrational state v_t associated with the ground-electronic state
E'—total energy in vibrational state v_t' associated with the upper-electronic state

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

E^a—activation energy for absorption
E^e—activation energy for emission
E^t—thermal activation energy
G_A—see (9.19)
G_n—normalized shape factor associated with the absorption or emission of phonons
G_m—maximum value of G_n
H—width at half-height (half-width) (7.4)
H—total Hamiltonian [see (3.12), (3.13), (5.4), and (5.10) for various meanings]
K—see (10.1a)
LST—Lyddane-Sack-Teller relation (see B, p. 86)
M_n—nth moment of the absorption curve (7.1)
N—number of imperfections per unit volume
Q_j—reduced coordinate of the jth mode associated with the upper state
$P(v_t)$—see (8.14)
$\mathbf{R}$—coordinate of all the nuclei
$\mathbf{R}_L$—value of $\mathbf{R}$ which minimizes V_L
$\mathbf{R}_n$—see (3.4a)
S—Huang-Rhys factor $\frac{1}{2}\sum_j \epsilon_j^2/\hbar\omega_j^3$ (4.3a) and (10.23)
T—kinetic energy operator for all the nuclei
T'—T which only operates on the χ's
T_e—kinetic energy operator for all the electrons
V—total potential energy of the system
V_e—potential energy due to an excess electron
V_I—potential energy due to a point imperfection
V_L—potential energy of a perfect lattice
$X_\alpha(k)$—actual coordinate of the kth particle in the αth direction
α—absorption coefficient
α_m—absorption coefficient at ϵ_m
β_j—see (8.14b)
ϵ—stands for an eigenvalue
ϵ_g—ground state eigenvalue of h_e
ϵ_j—see (3.18a)
ϵ_{jk}—see (3.18b)
ϵ_n—nth eigenvalue of h_e
ϵ_u—upper state eigenvalue of h_e
ϵ_v—vibrational eigenvalue
$\Delta\epsilon(\mathbf{R})=\epsilon_u(\mathbf{R})-\epsilon_g(\mathbf{R})$—see after (5.3) for special meaning in Secs. 5(a) and 14
$\Delta\epsilon$ or $\Delta\epsilon(\theta)=\Delta\epsilon(\mathbf{R}_g)$ in Part II
ϵ—also stands for a photon energy
ϵ_m—photon energy for maximum absorption
$\bar{\epsilon}$—see (7.2)
θ—absolute temperature
ν—*angular* frequency of the absorbed light
ν_{ug}—see (9.3a)
σ—absorption cross section
φ—electronic eigenfunction [φ (ground) and φ' (upper) are also used]
χ_j and χ_j'—ground- and upper-state vibrational eigenfunctions associated with the jth mode
χ and χ'—total vibrational eigenfunctions of the ground and excited states
Ψ—total eigenfunction of the system
ω—the effective angular frequency of the interacting phonons
ω_j—angular frequency associated with the jth mode

14. APPENDIX II. MEYER-PEKAR METHOD

This appendix relates the method developed for the trapped electron (5a) to the techniques used previously. Meyer (M8) has made the most extensive calculation. We now split $H_0(A)$ of (5.2) as follows:

$$H_L=T'+V_L+V_I \tag{14.1}$$

$$H_e=t+V_e(\mathbf{R}_I) \tag{14.2}$$

and

$$H_{Le}=V_e(\mathbf{R})-V_e(\mathbf{R}_I). \tag{14.3}$$

The division of H_0 here is not identical to the one made previously. Equation (14.1) determines a set of normal modes, Λ_j, from an expansion about the point defined by

$$\left[\frac{\partial}{\partial X_\alpha(k)}(V_L+V_I)\right]_{\mathrm{RI}}=0. \tag{14.4}$$

There is a close similarity [see Eqs. (3.12a) and (3.12b)] between H_L+H_e and $H_0(S)$ and between H_{Le} and $H_1(S)$. The $H_0(S)$ and $H_1(S)$ here correspond to the impurity model of Sec. 5. The potential energy term in $h_v(\mathbf{R})$ has been modified slightly. Meyer refers to H_{Le} as the lattice-center interaction. This term is actually given by $H_1(A)$.

An appropriate way to find a solution is to expand H_{Le}, as follows,

$$H_{Le}=\sum_j a_j\Lambda_j+\tfrac{1}{2}\sum_{jk} b_{jk}\Lambda_j\Lambda_k. \tag{14.5}$$

We assume that the eigenfunctions φ_n and eigenvalues $\Delta\epsilon_n$ of H_e are known at $\mathbf{R}_I$. The perturbation method is now used to obtain eigenvalues and eigenfunctions of H_e+H_{Le} for any $\mathbf{R}$. Thus,

$$\varphi_n(\mathbf{R})=\varphi_n+\sum_j\sum_m{}'\frac{\langle\varphi_m|\,a_j\,|\varphi_n\rangle}{\Delta\epsilon_n-\Delta\epsilon_m}\varphi_m\Lambda_j \\ +\text{higher terms.} \tag{14.6}$$

In the last term $m\neq n$, and we assume that the eigenvalues associated with H_e are nondegenerate. The argument $\mathbf{R}_I$ of φ and $\Delta\epsilon$ on the right-hand side of (14.6) has been omitted. The higher-order terms which are proportional to $\Lambda_j\Lambda_k$ arise from the use of second-order perturbation theory as well as from the last term of (14.5).

The $\varphi_n(\mathbf{R})$'s must form an orthogonal set with respect to $\mathbf{r}$ for a fixed value of $\mathbf{R}$. This follows since the complete series (14.6) gives eigenfunctions of the Hamiltonian H_e+H_{Le}. This was not evident to Meyer.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Associated with (14.6) is the eigenvalue

$$\Delta\epsilon_n(\mathbf{R})=\Delta\epsilon_n+\sum_j\langle\varphi_n|a_j|\varphi_n\rangle\Lambda_j$$
$$+\tfrac{1}{2}\sum_{jk}\langle\varphi_n|b_{jk}|\varphi_n\rangle\Lambda_j\Lambda_k$$
$$+\sum_m{}'\sum_{jk}\frac{1}{\Delta\epsilon_n-\Delta\epsilon_m}\langle\varphi_n|a_j|\varphi_m\rangle\langle\varphi_m|a_k|\varphi_n\rangle\Lambda_j\Lambda_k. \quad (14.7)$$

Terms of (14.7) may be identified with those which arise in an expansion about $\mathbf{R}_l$. We assume proper convergence. In such an expansion, terms similar to those in (3.18) appear. Thus,

$$\epsilon_j=\langle\varphi_n|a_j|\varphi_n\rangle \quad (14.8a)$$

and

$$\epsilon_{jk}=\langle\varphi_n|b_{jk}|\varphi_n\rangle$$
$$+\sum_m{}'\frac{1}{\Delta\epsilon_n-\Delta\epsilon_m}\langle\varphi_n|a_j|\varphi_m\rangle\langle\varphi_m|a_k|\varphi_n\rangle. \quad (14.8b)$$

Equation (14.8a) is a form of (3.16). The first term in (14.8b) was omitted by Meyer. One may use the ϵ_j's exactly as in Sec. 3 to determine the relation between the true q's and the Λ's. One should stress that H_{Le} does not arise from a true electron-phonon interaction but occurs only because a fictitious definition of the phonon field was used. On occasion the Λ's are assumed to have a very simple form, and the ϵ's obtained by these means correspond only very approximately with the real ones.

15. APPENDIX III. MEHLER'S FORMULA

Mehler's formula, Eq. (9.4), is "well known" in the theory of Hermite polynomials and has been used since it was discovered in 1866. Its proof is not available in standard texts. The steps are rather simple, providing one interchanges two integrals with an infinite sum. A proof due to Hardy is presented. It originally appears in a paper by Watson (W1). We shall not concern ourselves with the convergence of the series, so the proof as presented is not completely rigorous. A standard integral of interest is

$$\int_{-\infty}^{\infty}\exp[-a^2u^2+ibu]du=\frac{\sqrt{\pi}}{a}\exp[-b^2/4a^2]; \quad (15.1)$$

hence,

$$H_v=(-1)^v\exp[x^2]\frac{d^v}{dx^v}\exp[-x^2]$$
$$=\frac{(-2i)\exp[x^2]}{\sqrt{\pi}}\int_{-\infty}^{\infty}u^v\exp[-u^2+2ixu]du. \quad (15.2)$$

One would like to examine the sum

$$\sum_0^\infty t^v\chi_v(x)\chi_v(y)$$
$$=\sum_v\frac{1}{2^v v!\sqrt{\pi}}\exp\{-\tfrac{1}{2}(x^2+y^2)\}t^vH_v(x)H_v(y)$$
$$=\pi^{-\frac{1}{2}}\exp\{\tfrac{1}{2}(x^2+y^2)\}\sum_v\int\int\frac{(-2tuw)^v}{v!}$$
$$\times\exp\{-u^2-w^2+2ixu+2iyw\}dvdw. \quad (15.3)$$

For convenience, the usual $\omega/\hbar$'s which appear in the χ's have been omitted. v is the quantum state of χ_v. Hardy's device is to change the order of the sum and the integrals. Further, he replaces $\sum[(-2tuw)^v/v!]$ by $\exp\{-2tuw\}$. The convergence of (15.3) is such that this is permissible, provided $t^2<1$. Watson states this requirement but does not give details. One can see that (15.4) requires this relation. After this step, Eq. (15.1) is used twice, going from right to left. Thus,

$$\sum_v t^{v+\frac{1}{2}}\chi_v(x)\chi_v(y)$$
$$=t^{\frac{1}{2}}\pi^{-\frac{1}{2}}\exp\{\tfrac{1}{2}(x^2+y^2)\}$$
$$\times\int_{-\infty}^{\infty}\int\exp\{-u^2-2tuw-w^2+2ixu+2iyw\}dudw$$
$$=t^{\frac{1}{2}}\pi^{-1}\exp\{\tfrac{1}{2}(x^2-y^2)\}$$
$$\times\int\exp\{-(1-t^2)u^2+2i(x-yt)u\}du$$
$$=\pi^{-\frac{1}{2}}\left[\frac{t}{1-t^2}\right]^{\frac{1}{2}}\exp\left\{\frac{x^2-y^2}{2}-\frac{(x-yt)^2}{1-t^2}\right\}$$
$$=\pi^{-\frac{1}{2}}\left[\frac{t}{1-t^2}\right]^{\frac{1}{2}}\exp\left\{-\frac{(x^2+y^2)}{2}\left(\frac{1+t^2}{1-t^2}\right)+xy\frac{2t}{1-t^2}\right\}. \quad (15.4)$$

If we set $t=e^{\xi}(\xi>0)$, Eq. (15.4) gives (9.4) after some elementary transformations which use the properties of the hyperbolic functions.

16. APPENDIX IV. PEKARIAN CURVE

Properties of Pekarian curves, Eq. (9.21), are discussed here. This equation gives the relative probability for a transition from $v_t=0$ to any $v_t'=p$ (Eq. 9.15). Since the number of modes does not enter into the problem, we again use the CC model as an illustration. The Pekarian shape is not limited to this case but also applies to the Fröhlich and LM models. The only serious limitation is the use of Eq. (9.7).

Absorption shapes do not seem to be completely symmetric (K2a, p. 118), and one may inquire as to the symmetrical properties of the Pekarian curve. Consider first the case where $S=20$. The most probable transi-

$\frac{S^p}{p!}\left(\frac{S^S}{S!}\right)^{-1}$	$\frac{(20)^3}{(21)(22)(23)}$	$\frac{(20)^2}{(21)(22)}$	$\frac{20}{21}$	1	1	$\frac{19}{20}$	$\frac{19(18)}{(20)^2}$	$\frac{(17)(18)(19)}{(20)^3}$
Transition probability	0.7529	0.8658	0.9524	1	1	0.9500	0.8550	0.7268

tions occur for $v_t'=S-1$ and S. If one assumes that the transition probability for these jumps is unity, then one may obtain the properties in Table VI. The transition probabilities do not lie symmetrically about the midpoint, which is very nearly at 19.5.

To stress the asymmetry of the problem, Fig. 9 is included. The left-hand side is similar to Fig. 6 except that the upper state has been shifted twice as much, and only the case where $v_t=0$ is considered. On the right-hand side $|\{\chi'|\chi\}|^2$ is plotted against v_t'. On the x axis v_t' increases in going from right to left, in agreement with experimental procedure. It is evident that $\epsilon_v-\epsilon_m\neq\epsilon_m-\epsilon_r$ so that the Pekarian curve is asymmetric.

In Fig. 10 three Pekarian curves for $S=3$, 10, and 20 are plotted. On the curves the ratio of $\epsilon_v-\epsilon_m$ to $\epsilon_m-\epsilon_r$ is noted. These values show that the curve is slightly lopsided for all values of S and resembles a double Gaussian. The violet side is indeed almost a perfect Gaussian.

To calculate various factors associated with a Pekarian curve, we use (9.17) and let $\theta=0$. The following formula is obtained:

$$|\{\chi_p'|\chi_0\}|^2=Ge^{-s}=(S^p/p!)e^{-s}. \tag{16.1}$$

0 and p are the total vibrational quantum numbers of the states χ and χ'. The term $1/\omega$ has not been included. It determines the width (or height) of the curve. Also, we set $\omega=\hbar\omega=1$. Using (10.9) and (10.24b) we note that,

$$\sum_{v_t'}|\{\chi'|\chi_0\}|^2=1 \tag{16.2}$$

and

$$m^2=S. \tag{16.3}$$

Since $M_0=1$ it is temperature independent [Eq. (10.9)]. Hence, we know that the relation

$$\sum_{v_t}P(v_t)\sum_{v_t'}|\{\chi'|\chi_0\}|^2=1 \tag{16.4}$$

holds for any θ. Now, since

$$\sum_{v_t}P(v_t)=1, \tag{16.5}$$

we conclude that

$$\sum_{v_t'}|\{\chi'_{v_t'}|\chi_{v_t}\}|^2=1 \tag{16.6}$$

for any v_t. This is a sum-rule which has one surprising feature—it does not involve the frequency. In atomic spectra, the sum-rules involve the transition frequency. This means that we may not accept the atomic sum-rules without further careful considerations.

By numerical calculation we obtain Table VII. Here

TABLE VII. Some properties of Pekarian curves.

S	p_l	$(e^{-s}G)_{\max}$	H	Area	$H^2/m^2=H^2/S$	$a_s(P)$
3	2.5	0.229	4.18	1	5.82	1.0
5	4.5	0.180	5.28	1.01	5.58	1.06
10	9.5	0.126	7.46	1.00	5.57	1.07
20	19.5	0.0892	10.56	1.01	5.58	1.07
30	29.5	0.0728	12.92	1.01	5.56	1.07

the lines of Fig. 9 have been replaced by the envelope curve. Column 3 is the value of the absorption at the peak (at p_l).†††† The fifth column is the area (planimeter) under the curves when the factor e^{-s} is included. This area might be slightly larger than unity because we are replacing a sum by a smooth curve. At $S-\frac{1}{2}$ the envelope is larger than the values at S or at $S-1$. To obtain the sixth column, use was made of (16.3), and the seventh is obtained from the definition of Smakula's constant found in Sec. 7, combined with (16.2). Columns 6 and 7 should be compared with the value found for the Gaussian shape, that is, 5.545 and 1.064. The Lorentzian value of a_s is 1.57. The deviation from the Gaussian values is very small. The variation for small values of S is probably real; however, we attach no importance to the slight deviation found in the last four rows. One may readily superimpose various Pekarian curves unless S is smaller than 10.

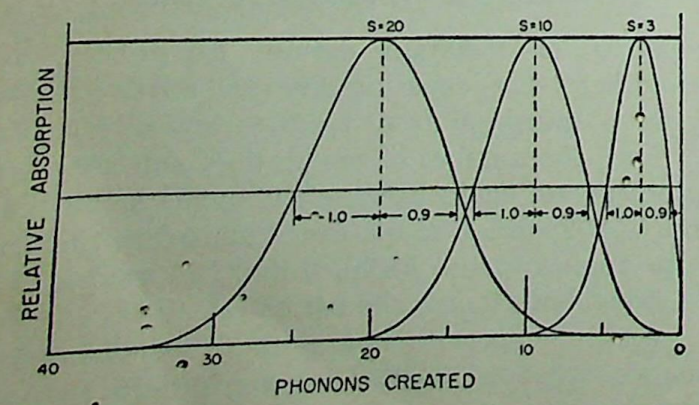

FIG. 10. Three Pekarian curves for various values of S. Note the lack of symmetry.

17. APPENDIX V. EFFECTS WHICH OCCUR WHEN f IS NOT A CONSTANT

We now consider what happens to the equations of Sec. 10 when the simplifying assumptions regarding f

†††† Since no fine structure is observed p will not be limited to integer values.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

are removed. One might use the Lax-Meyer method throughout, but the algebraic complexities become too involved. In Sec. 10 we replaced $\exp(iH_u t/\hbar)\times\exp(-iH_g t/\hbar)$ by $\exp[i(H_u-H_g)t/\hbar]$. It is correct only to terms in $(H_u-H_g)^2$. This arises because $\exp(iH_u t/\hbar)$ is only a shorthand notation for an infinite series and the terms in the two sums do not in general commute. Hence, this method is not used in the first section of this Appendix.

The two problems are: what happens to the expression for $\bar{\epsilon}$ and m^2 when f becomes a linear function of the frequency, or a linear function of the q's?

(a) Oscillator Strength Depends on the Frequency

First, we consider the effects of having the oscillator strength proportional to the frequency. For this purpose, the dipole matrix M is introduced.‡‡‡‡ It is assumed to be a constant. Further, we limit our considerations to the case where one may assume a single frequency and omit the ϵ_{jk}'s, i.e., the situation treated in Sec. 9.

Combining (8.16), (8.18), and (9.8) results in

$$\alpha(\nu)=bN\frac{4\pi^2}{3\hbar c}|\langle\varphi'|e\mathbf{r}|\varphi\rangle|^2\nu G(\nu)$$

$$=K'M^2\nu\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{-i(\nu-\nu_{ug})t}$$

$$\times\exp\{-S[\coth\tfrac{1}{2}\beta-i\sin\omega t-\coth\tfrac{1}{2}\beta\cos\omega t]\}dt, \quad (17.1)$$

where

$$K'=4\pi^2bN/3\hbar c \quad (17.1a)$$

and

$$M=\langle\varphi'|e\mathbf{r}|\varphi\rangle. \quad (17.1b)$$

Since our interest is in the moments of the distribution, we assume that the absorption is a series of delta functions.

Taking the Fourier transformation of $\alpha(\nu)/\nu$, one arrives at

$$\int_{-\infty}^{\infty}[\alpha(\nu)/\nu]e^{i\nu t}d\nu=K'M^2e^{i\nu_{ug}t}$$

$$\times\exp\{-S[\coth\tfrac{1}{2}\beta-i\sin\omega t-\coth\tfrac{1}{2}\beta\cos\omega t]\}. \quad (17.2)$$

From this it follows that

$$M_0=(\hbar/i)\left\{(\partial/\partial t)\int_{\infty}^{\infty}[\alpha(\nu)/\nu]e^{i\nu t}d\nu\right\}_{t=0}$$

$$=\hbar K'M^2\{\nu_{ug}+S\omega\}=K'M^2\Delta\epsilon=K\hbar\bar{f}, \quad (17.3)$$

where

$$\bar{f}=2m\bar{\nu}M^2/3e^2\hbar \quad (17.3a)$$

and

$$\bar{\nu}=\Delta\epsilon/\hbar. \quad (17.3b)$$

Use has been made of (10.1a) and (10.14). (17.3) should be compared to (10.9). Further,

$$M_1=-\hbar^2\{(\partial^2/\partial t^2)\textstyle\int_{-\infty}^{\infty}[\alpha(\nu)/\nu]e^{i\nu t}d\nu\}_{t=0}$$
$$=K'M^2[(\Delta\epsilon)^2+\hbar^2\omega^2S\coth\tfrac{1}{2}\beta]$$
$$=K'M^2\Delta\epsilon[\Delta\epsilon+(\hbar^2\omega^2/\Delta\epsilon)S\coth\tfrac{1}{2}\beta] \quad (17.4)$$

and

$$M_2=-(\hbar^3/i)\{\partial^3/\partial t^3)\textstyle\int_{-\infty}^{\infty}[\alpha(\nu)/\nu]e^{i\nu t}d\nu\}_{t=0}$$
$$=K'M^2\Delta\epsilon[(\Delta\epsilon)^2+3\omega^2\hbar^2S\coth\tfrac{1}{2}\beta$$
$$+(\omega^3\hbar^3/\Delta\epsilon)S]. \quad (17.5)$$

Further,

$$\bar{\epsilon}=\Delta\epsilon+(\hbar^2\omega^2/\Delta\epsilon)S\coth\tfrac{1}{2}\beta \quad (17.6)$$

and

$$m^2=\omega^2\hbar^2S\{\coth\tfrac{1}{2}\beta+(\omega\hbar/\Delta\epsilon)$$
$$-[\hbar^2\omega^2/(\Delta\epsilon)^2]S\coth^2\tfrac{1}{2}\beta\}. \quad (17.7)$$

Equation (17.6) shows that $\bar{\epsilon}$ shifts to the *violet* with rising temperatures. The shift is very small, since $\hbar^2\omega^2S/\Delta\epsilon$ is of the order of 0.0015 ev. If $\hbar\omega$ were 0.08 ev and $S\approx30$ this term would be observable. This might occur in LiF if the transverse optical mode were important for the interaction. m^2 now has a constant term and a term proportional to $\coth^2\frac{1}{2}\beta$. The negative sign on this term means that m^2 can be negative at *very* high temperatures. This anomalous situation arises from the mathematical formulation and has nothing to do with actual emission. By returning to (17.1) we see that $\alpha(\nu)<0$ if $\nu<0$. Since the mathematical techniques require integration from $-\infty$ to $+\infty$, the integral $\int_{-\infty}^{\infty}(\nu-\bar{\nu})^2\nu G(\nu)d\nu$ can be negative in spite of the fact that $(\nu-\bar{\nu})^2>0$. The author expects that both additional terms in (17.7) are very small and will not be detected experimentally.

The form (17.7) is not valid at extremely high temperatures, say 5000°K, if $(\hbar\omega)^2S/(\Delta\epsilon)^2$ is of the order of 10^{-3}. For the F center in KCl this term is of the order of 8×10^{-4}, and our interests are limited to temperatures below 600°K. The above calculations are most probably valid under these conditions. They indicate that the assumption that f is independent of ν does not have an important influence on the moments. In the language of Dexter (D1, p. 392), we have shown when the "narrow-band approximation" is valid.

(b) Oscillator Strength Depends on the q's

In the case where $f^{\frac{1}{2}}$ depends on the normal modes, the solution is straightforward but extremely laborious. To simplify the problem somewhat the CC model will be used, thus $f^{\frac{1}{2}}$ is taken in the form

$$f^{\frac{1}{2}}=f_0^{\frac{1}{2}}+f_1^{\frac{1}{2}}q. \quad (17.8)$$

Equation (17.8) is a possible assumption, and it is

‡‡‡‡ For simplicity of notation M is considered to be a real scalar.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

made without any profound theoretical justification? In (17.8) q is the coordinate associated with the ground state. The normal mode for the excited state is taken in the form $q-\Delta q=Q$. Further, we again assume that the ϵ_{jk}'s are very small so that the frequencies in both states are equal. As before, $f^{\frac{1}{2}}$ is taken as real; further, our considerations will be limited to terms in $f_1^{\frac{1}{2}}$. Equation (10.6) cannot be used, and we require some more complex equations given by Lax (L1), namely,

$$M_0=\hbar K \operatorname{Av}\{\chi|f|\chi\} \tag{17.9}$$

$$M_1=\hbar K \operatorname{Av}\{\chi|f^{\frac{1}{2}}H_u f^{\frac{1}{2}}-fH_g|\chi\} \tag{17.10}$$

and

$$M_2=\hbar K \operatorname{Av}\{\chi|f^{\frac{1}{2}}H_u^2 f^{\frac{1}{2}} -2f^{\frac{1}{2}}H_u f^{\frac{1}{2}}H_g+fH_g^2|\chi\}. \tag{17.11}$$

Equation (17.10) is equivalent to (10.12) provided

$$\{\chi|H_uH_g|\chi\}=\{\chi|H_gH_u|\chi\} \tag{17.12}$$

when f is independent of q.

To establish (17.12) we require some of the properties of the χ's. One may show (M7, p. 121 and 358)§§§§

$$(\partial/\partial q)\chi_v=(\omega/\hbar)^{\frac{1}{2}}\{(\tfrac{1}{2}v)^{\frac{1}{2}}\chi_{v-1}-[\tfrac{1}{2}(v+1)]^{\frac{1}{2}}\chi_{v+1}\} \tag{17.13}$$

$$q\chi_v=(\hbar/\omega)^{\frac{1}{2}}\{[\tfrac{1}{2}(v+1)]^{\frac{1}{2}}\chi_{v+1}+(v/2)^{\frac{1}{2}}\chi_{v-1}\}. \tag{17.14}$$

Hence

$$\{\chi|q(\partial/\partial q)|\chi\}=-\tfrac{1}{2} \tag{17.15}$$

and

$$\{\chi|TV_{u,g}|\chi\}=\{\chi|V_{u,g}T|\chi\}. \tag{17.16}$$

To establish (17.16) we have used (3.26) but placed no restriction on the v's; hence, (17.16) applies to the case considered in Sec. 10 and is the justification for Eq. (10.12). A similar argument has not been found for terms in $(H_u-H_g)^3$, and the technique of Sec. 10 requires lengthy and complex algebra.

Returning to (17.8), we note from (17.13) and (17.14) that our interest is limited to even terms of the q's, i.e., such as q^2 or $q(\partial/\partial q)$, not q^3 or $\partial/\partial q$. Hence, substituting (17.8) in (17.9), one obtains

$$M_0=\hbar K f_0. \tag{17.17}$$

Had terms in f_1 been included, we would have found that M_0 is temperature *dependent*. Now, substituting into (17.10), we obtain

$$M_1=\hbar K \operatorname{Av}\{\chi|f_0(V_u-V_g) -2f_0^{\frac{1}{2}}f_1^{\frac{1}{2}}\omega^2(\Delta q)q^2|\chi\}, \tag{17.18}$$

$$=\hbar K(f_0\Delta\epsilon-\omega\hbar\Delta q f_0^{\frac{1}{2}}f_1^{\frac{1}{2}}\coth\tfrac{1}{2}\beta) \tag{17.19}$$

$$=\hbar K f_0\left\{\Delta\epsilon-\omega\hbar\left[\frac{M(d)-M(a)}{M(a)}\right]\coth\tfrac{1}{2}\beta\right\}. \tag{17.19a}$$

$M(a)$ and $M(d)$ are dipole moments at positions (a) and (d) of Fig. 2. The ratio $[M(d)-M(a)]/M(a)$ must be of the order of 0.1 or much less, probably much less. The second term of (17.19a) cannot possibly be larger than 0.001, and we would not expect to detect it experimentally. Further,

$$M_2=\hbar K \operatorname{Av}\{\chi|f_0(V_u-V_g)^2+f_0^{\frac{1}{2}}f_1^{\frac{1}{2}}[TV_uq+V_uTq +qTV_u-3qV_uT+2q(V_u-V_g)^2]|\chi\}. \tag{17.20}$$

Since

$$\{\chi|TV_uq|\chi\}=\{\chi|qV_uT|\chi\} \tag{17.21a}$$

$$\{\chi|V_uTq|\chi\}=\{\chi|qTV_u|\chi\} =\{\chi|qV_uT|\chi\}-(\hbar^2/2)\omega^2\Delta q, \tag{17.21b}$$

we have

$$M_2=\hbar K \operatorname{Av}\{\chi|(V_u-V_g)^2f_0+f_0^{\frac{1}{2}}f_1^{\frac{1}{2}}[2q(V_u-V_g)^2 -\hbar^2\omega^2\Delta q]|\chi\}. \tag{17.22}$$

The third term gives rise to a temperature independent factor in m^2. Taking the indicated average in (17.22) results in

$$M_2=\hbar K\{f_0[(\Delta\epsilon)^2+\hbar^2\omega^2S\coth\tfrac{1}{2}\beta] -\Delta q f_0^{\frac{1}{2}}f_1^{\frac{1}{2}}[2\Delta\epsilon\hbar\omega\coth\tfrac{1}{2}\beta+\hbar^2\omega^2]\}. \tag{17.23}$$

Returning to (7.3) we obtain

$$m^2=\hbar^2\omega^2[S\coth\tfrac{1}{2}\beta-\Delta q(f_1^{\frac{1}{2}}/f_0^{\frac{1}{2}})]. \tag{17.24}$$

To estimate the magnitude of the second term we again use Fig. 2. From the definitions of the f's and Δq one obtains

$$\Delta q f_1^{\frac{1}{2}}/f_0^{\frac{1}{2}}=[M(d)-M(a)]/M(a). \tag{17.25}$$

The maximum correction term that one may expect in (17.24) is 0.1. Such small values could barely be detected experimentally (Sec. 10). Meyer (M8) suggested that this term equals -10. Such large values cannot be explained readily by the theory.

The conclusion is rather straightforward. The assumptions used in arriving at (8.18) are most probably oversimplified. However, they do not produce major changes in the moments of the distribution or in the shapes. Some corrections to the moments have been worked out here. They are certainly too small to be measured, and the author cannot envisage any theoretical calculation which will be sufficiently accurate to determine them. One may show experimentally, however, that M_3 has a complex temperature dependence (K4). The theoretical reason for this is at present unknown. The author believes this will come out of a more realistic model.

§§§§ The subscript is the vibrational quantum number.

1. INTRODUCTION

THE mechanism of energy transfer from one constituent to the other in solids, solutions, and gaseous mixtures has created considerable interest during recent years. Until very recently these discussions[1,2] were confined mostly to the inorganic phosphors in general, and alkali halides in particular. Along with the inorganic atoms and molecules, more than a few experimental results on benzene and benzene derivatives are also reported in the literature.[3–6] For instance, the fluorescence of indigo vapor is not excited by light of wavelength between 2700 to 2400 A, but in the presence of aniline vapor it gives violet indigo fluorescence. The incident light is first absorbed by the aniline vapor and then the absorbed energy is transferred to the indigo vapor. Similarly, aniline in presence of benzene vapor gives strong fluorescence under weak excitation. Zinc radiation at 2500 A produces only a very weak fluorescence in aniline vapor extending from 2850 to 2500 A. In a mixture of aniline and benzene vapor the benzene fluorescence is weak though it is easily excited by primary light of wavelength 2500 A, while the aniline fluoresces strongly. Apparently, the transfer of excitation energy from the benzene to the aniline molecules has high efficiency. These are instances of sensitized fluorescence which are commonly described as the process whereby an impurity atom or molecule (activator) devoid of any appreciable absorption band in a given spectral region is made to radiate upon absorption of excitation energy in this region by the host lattice or an impurity atom or molecule (sensitizer) embedded in it. In all cases of sensitization, the problem which is of the most fundamental significance is as follows: What is the mechanism of propagation of the excitation energy from the sensitizer to the activator and its ultimate transfer? Where the sensitizer and the activator are close to each other, the excitation energy does not have to move far and the processes of propagation and transfer both take place at nearly the same position in the lattice. There are also cases of sensitized luminescence where absorption of the exciting energy takes place all over the matrix lattice while the luminescence transitions occur in or near the few activators. These cases are characterized by propagation of energy through the lattice over a considerable distance before transfer of the excitation energy can occur. There are four distinct processes by which transfer of the excitation energy can take place. They are (a) photon absorption and reabsorption, known as photon cascade; (b) collision; (c) exciton migration; and (d) electron and hole migration. We discuss them briefly, bringing out the conditions to which each is subject. Particular emphasis is given to the discussion of anthracene-naphthacene and anthracene-naphthalene systems in crystals.

(a) Photon Absorption and Reabsorption

This mechanism of energy transfer, also called the photon cascade process, becomes of quantitative importance in a system if there exists strong overlap between the emission and the absorption spectra and

if the system has a high absorption coefficient in the area of overlap, comparable with that at the wavelength of excitation. The system may be a pure one containing no foreign constituents, the region of overlap being between the emission and the absorption spectra of the constituents of the pure system. If the system is an impure one, containing impurity atoms or molecules embedded in it, the region of overlap may be provided by the emission spectrum of the pure system and the absorption spectrum of impurity constituents. If we consider such a crystal system, the part of the primary molecular fluorescence that is emitted in the region of overlap, is practically reabsorbed by the crystal within a small fraction of its thickness. This reabsorbed radiation is re-emitted as fluorescence by the molecules which absorbed it. A fraction of it suffers reabsorption by succeeding layers of molecules, these processes of emission and reabsorption follow each other until all the excitation energy is either transformed into fluorescence outside the region of overlap so as to escape from the crystal as technical fluorescence or is thermally dissipated by internal conversion.

A quantitative formulation of the mechanism was developed by Birks[7] to explain the photofluorescent and scintillation properties of organic materials. Let us consider a mixed crystal containing solute molecules A immersed in solvent molecules S. On the photon cascade theory, the processes shown in Table I occur in the crystal, assuming that the exciting radiation is absorbed totally by S and that S does not absorb the fluorescence radiation of A.

When only processes 2 and 3 (see Table I) compete, there results the molecular fluorescence of S. Its quantum efficiency η_{0s} is given by

$$\eta_{0s}=\frac{1}{1+(K_{is}/K_{fs})}. \tag{1}$$

When the competing processes are described by 2, 3, 4, 5, and 9, the primary fluorescence of S is reabsorbed and re-emitted and only a part of the primary fluorescence S escapes from the crystal as technical fluorescence. The quantum efficiency η_{es} of this is given by

$$\eta_{es}=\frac{\eta_{0s}}{1+(K_S/K_{es})+(K_A/K_{es})[A]}+\frac{K_S}{K_{es}}\left\{\frac{\eta_{0s}}{1+(K_S/K_{es})+(K_A/K_{es})[A]}\right\}^2+\left(\frac{K_S}{K_{es}}\right)^2\left\{\frac{\eta_{0s}}{1+(K_S/K_{es})+(K_A/K_{es})[A]}\right\}^3=\frac{\eta_{0s}}{1+(1-\eta_{0s})(K_S/K_{es})+(K_A/K_{es})[A]}. \tag{2}$$

[7] J. B. Birks, Phys. Rev. 94, 1957 (1954).

TABLE I. Photon transfer process.

Process	Relative ratio[a]	Description of process
1. $S+h\nu \rightarrow S^*$	1	Excitation by light
2. $S^* \rightarrow S+h\nu_s$	$K_{fs}[S^*]$	Fluorescence of S
3. $S^* \rightarrow S$	$K_{is}[S^*]$	Internal quenching of S
4. $S+h\nu_s \rightarrow S^*$	$K_sK_{fs}[S^*]$	Self-absorption of S
5. $A+h\nu_s \rightarrow A^*$	$K_AK_{fs}[S^*][A]$	Absorption of A
6. $A^* \rightarrow A+h\nu_A$	$K_{fA}[A^*]$	Fluorescence of A
7. $A^* \rightarrow A$	$K_{iA}[A^*]$	Internal quenching of A
8. $A+h\nu_A \rightarrow A^*$	$K_AK_{fA}[A^*][A]$	Self-absorption of A
9. $h\nu_s \rightarrow$	$K_{es}K_{fs}[S^*]$	Escape of $h\nu_s$
10. $h\nu_A \rightarrow$	$K_{eA}K_{fA}[A^*]$	Escape of $h\nu_a$

[a] Here Brackets stand for concentrations in molecules per solvent molecule, S^* and A^* for excited molecules of S and A, and $K=(1/t)$ for the probability of a process of decay time t, i.e., number of events describing the process, that happen per unit time.

In the absence of internal quenching $K_{is}=0$ and $\eta_{0s}=\eta_{0A}=1$, so that (2) is reduced

$$\eta_{es}=\frac{1}{1+(K_A[A]/K_{es})}. \tag{3}$$

The quantum yield for transfer, i.e., the ratio of the number of photons transferred per second from S to A to the number of photon absorbed by S per second, neglecting nonradiative transactions in S becomes, in the case of molecular fluorescence,

$$\eta_{0T}=K_A[A]/K_S. \tag{4}$$

The molecular fluorescence quantum efficiency η_{0A} of A is given by

$$\eta_{0A}=\frac{1}{1+(K_{iA}/K_{fA})}. \tag{5}$$

The quantum efficiency (η_{eA}) of escape of (A) technical fluorescence is given by

$$\eta_{eA}=\frac{\eta_{es}\eta_{0A}(K_A/K_{es})[A]}{1+(1-\eta_{0A})(K_A'/K_{eA})[A]}. \tag{6}$$

In the absence of internal quenching, $K_{iA}=0$ and $\eta_{0s}=\eta_{0A}=1$ so that we have for (6)

$$\eta_{eA}=\eta_{es}(K_A/K_{es})[A]=1-\eta_{es}=\frac{(K_A/K_{es})[A]}{1+(K_A/K_{es})[A]}. \tag{7}$$

Here the quantities K_{es}, K_S, and $K_A(A)$ are interrelated by

$$K_{es}+K_S+K_A(A)=1.$$

They are dependent upon the relative absorption coefficients of S and A for the fluorescence of S and on the crystal size.

In pure crystal phosphors, processes 1, 2, 3, 4, and 9 are in operation. The molecular quantum efficiency (suffix S is now dropped) remains unchanged while the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

technical quantum efficiency η_e takes the form

$$\eta_e = \frac{\eta_0}{1+(1-\eta_0)(K/K_e)} = \frac{1}{1+(K_i/K_eK_f)}; \quad [\because \; K+K_e=1]. \tag{8}$$

If internal quenching is not present, the molecular photofluorescence decay time $(t_f)_{00}=1/K_f$; internal quenching, if present, reduces it to $(t_f)_0$ given by

$$(t_f)=\frac{(t_f)_{00}}{1+[(t_f)_{00}/t_i]}=\eta_0(t_f)_{00}. \tag{9}$$

In case of a large thick crystal, stepwise self-absorption lengthens the duration of the interval between the moment of primary excitation and the moment of escape of fluorescence so that the technical photofluorescence decay time t_f is increased to

$$t_f=\frac{(t_f)_{00}}{K_e+[(t_f)_{00}/t_i]}. \tag{10}$$

When internal quenching is small enough to make $(t_f)_{00} \ll t$; (8) and (10) may be expressed approximately as follows:

$$t_f=\eta(t_f)_0 \tag{11}$$

and

$$\eta_e=(\eta_0)^N. \tag{12}$$

Here $N=1/K_e$ represents the average number of steps of molecular emissions passed before escape of technical fluorescence. The molecular and technical photofluorescence quantities $(t_f)_0$ and (t_f) can be obtained from measurements on microcrystalline and thick crystal specimens and thus N can be determined. Comparison of the molecular and the technical photofluorescence spectra leads to a determination of N.

(b) Collision Process

This mechanism was proposed by Cario and Franck[8] and to account for the disappearance of fluorescence of a gas due to the presence of foreign gas molecules. In this process when an excited atom or molecule collides during the lifetime of its excited state with a slow electron, it may give away its excitational energy to the electron, without any radiation, the products of the collision being an electron with enhanced kinetic energy and an unexcited atom or molecule. When the collision partner is a normal atom or molecule, the excited atom or molecule may give away a quantum of energy (E_2-E_1) to the unexcited one and the latter may take up the energy either as energies of translation, excitation or both; there being no loss of energy during the process as radiation. Such radiationless transfer of excitation energy is called a collision of the second kind, as distinguished from a collision of the first kind in which excitation is produced. The mechanism, demonstrated in gases by Franck, Cario, and many others, has been shown to take place also in some organic solutions.[3,9]

The quantum-mechanical theories of this transfer process as formulated by Perrin[10] and Forster[11], are based on resonance between allowed electric dipole transitions in the sensitizer and the activator. The resonance theory is extended by Dexter[12] to include cases of energy transfer in which an activator having a suitable emission spectrum can be made to fluoresce with energy transferred from an absorbing sensitizer despite the fact that the activator is forbidden direct absorption of energy. The transfer mechanisms of importance are by overlap of the electric dipole fields of the sensitizer and the activator, overlap of the dipole field of the former and the quadrupole field of the latter, and exchange effects, producing, respectively, sensitization of about 10^3-10^4, about 10^2, and about 30 lattice sites in a crystal surrounding each sensitizer. Dexter's theory is applicable to impurity sensitization both in solid and liquid systems. He adopts the physical model of a crystal in which the sensitizing impurity atoms or ions, of atomic concentration x_s, and the activators of atomic concentration x_a, are randomly arranged at suitable lattice sites, without mutual interaction. The time-dependent perturbation method of quantum mechanics gives the probability of transition of a system from its initial to final state as

$$(2\pi/h)|\langle H_1\rangle|^2\rho_E, \tag{13}$$

where $\hbar$ is Planck's constant divided by 2π, H_1, the matrix element of the perturbation to the Hamiltonian and ρ_E the density of final states. In this case the initial state ψ_1 is identified with the configuration of the system in which the sensitizer S is in the excited state ψ_s' while the activator A is in its ground state ψ_a and the final state ψ_2 is the configuration in which S is in its ground while A is excited to the state ψ_a'. Thus the probability that the energy of excitation is transferred from a particular sensitizer S to a particular activator A has the form,

$$P_{sa}=(2\pi/h)\rho_E\left|\int\psi_1^*H_1\psi_2 d\tau\right|^2, \tag{14}$$

as long as the states ψ_1 and ψ_2 are of the same energy.

To take account of the lack of definition of the initial and final levels of S or A caused by lattice vibrations, the wave functions are normalized on an energy scale and the density of states factor ρ_E is included within the

[8] G. Cario and J. Franck, Z. Physik 17, 202 (1928).

[9] J. Franck and R. Livingston, Revs. Modern Phys. 21, 505 (1949).

[10] F. Perrin, J. phys. radium 7, 1 (1936).

[11] Th. Forster, Ann. phys. 2, 55 (1948); Z. Electrochem. 53, 93 (1949).

[12] D. L. Dexter, J. Chem. Phys. 21, 836 (1953).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

normalization parameters. It is convenient to normalize the initial states of S and A (ψ_s' and ψ_a) and to express by the functions $p_s'(w_s')$ and $p_a(w_a)$ the probabilities that S is in the particular energy state denoted by w_s' and that A is in the state w_a so that

$$\int |\psi_s'(w_s')|^2 d\tau = \int |\psi_a(w_a)|^2 d\tau,$$
$$\int_0^{\alpha} p_s'(w_s')dw_s' = \int p_a(w_a)dw_a = 1. \tag{15}$$

The final states of S and A (ψ_s and ψ_a') are normalized on the energy scale by the following:

$$\frac{1}{\Delta w}\int_w^{w+dw} dw_s \int |\psi_s(w_s)|^2 d\tau = 1$$
$$\frac{1}{\Delta w}\int_w^{w+\Delta w} dw_a' \int |\psi_a'(w_a')|^2 d\tau = 1. \tag{16}$$

The properly antisymmetrized initial and final states wave functions describing S and A can now be written as

$$\psi_1(w_s', w_a) = \frac{1}{\sqrt{2}}\begin{vmatrix} \psi_s(\bar{r}_1, w_s') & \psi_s'(\bar{r}_2, w_s') \\ \psi_a(\bar{r}_1, w_a) & \psi_a(\bar{r}_2, w_a) \end{vmatrix}$$
$$\psi_2(w_s, w_a') = \frac{1}{\sqrt{2}}\begin{vmatrix} \psi_s(\bar{r}_1, w_s) & \psi_s(\bar{r}_2, w_s) \\ \psi_a'(\bar{r}_1, w_a') & \psi_a'(\bar{r}_2, w_a') \end{vmatrix}, \tag{17}$$

where only two electrons are involved in the transitions.

According to the Franck-Condon principle, an electronic transition in which the electronic excitation energy is lost to the lattice has small probability of occurrence, because of the condition of energy equality of the states ψ_1 and ψ_2. Under these conditions the transition probability P_{sa} should contain a Dirac delta function $\delta(E_1 - E_2)$, as a factor where $E_1 = w_s' - w_s$ and $E_2 = (w_a' - w_a)$ are the excitation energy on S in the state ψ_1, and that on A in the state ψ_2, respectively. The total probability of energy transfer from S to A becomes

$$P_{sa} = \left(\frac{2\pi}{\hbar}\right)\sum_1\sum_2 (g_s'g_a)^{-1} \times \int dw_a' \int dw_s \int dw_a p_a(w_a) \int dw_s' p_s'(w_s') \times |\langle H_1(w_s', w_a; w_s, w_a')\rangle_{12}|^2 \times \delta[(w_s' - w_s) - (w_a' - w_a)], \tag{18}$$

where g_s' and g_a are the degeneracies of the level of S and of the level of A, respectively.

Calculating by means of the S function and substituting $E = E_1 = E_2$, we have

$$P_{sa} = \left(\frac{2\pi}{\hbar}\right)\sum_1\sum_2 (g_s'g_a)^{-1} \times \int dE \int dw_a p_0(w_a) \int dw_s' p_s'(w_s') \times |\langle H_1(w_s', w_a; w_s' - E, w_{a+E})\rangle|^2. \tag{19}$$

The interaction between A and S can be expressed as the sum of all the Coulomb interactions of the outer electrons and the core of A with those of S, properly reduced by the dielectric constant K of the medium. Expansion of this sum in a Taylor series around the vector $\mathbf{R}$, which separates the nuclei of A and S, reduces the interaction Hamiltonian to the form

$$H_1(\bar{R}) = \left(\frac{e^2}{KR^3}\right)\{\bar{r}_s\cdot\bar{r}_a - 3(\bar{r}_s\cdot\bar{R})(\bar{r}_a\cdot\bar{R})/R^2\} + \left(\frac{3e^2}{2KR^4}\right)\{\sum_{i=1}^{3}(R_i/R)r_{ai}^2 r_{si}(-3+5R_i^2/R^2) + 10(XYZ/R^3)(x_a y_a z_s + x_a z_a y_s + y_a z_a x_s) + \sum_{i\neq j}^{3}\sum^{3}[(R_j/R) - 5R_i^2 R_j/R^3] \times [-r_{ai}^2 r_{sj} - 2r_{ai}r_{aj}r_{si}]\}, \tag{20}$$

where $\bar{r}_s = \sum_m \mathbf{r}_{s0m}$ refers to all electrons on S measured from its nucleus and so with $\mathbf{r}_a = \sum_n \mathbf{r}_{an}$.

Electric Dipole-Dipole Interaction

The first curly brackets in Eq. (20) are the dipole-dipole interaction term. Inserting this into Eq. (17), one can have

$$P_{sa}(dd) = \left(\frac{2\pi}{\hbar}\right)\sum_1\sum_2\left(\frac{e^4}{K^2R^6}\right)(g_s'g_a)^{-1} \times dE \int dw_a p_a(w_a) \int dw_s' p_s'(w_s') \times \langle\bar{r}_s\rangle\langle\bar{r}_a\rangle - 3(\langle\bar{r}_s\rangle\cdot R)|(\langle r_a\rangle R)|^2, \tag{21}$$

where the matrix element, $\langle\bar{r}_s\rangle$ stands for

$$\langle\bar{r}_s(w_s', w_s' - E)\rangle_{isfs}$$

and so with (r_a). Average of the absolute square of the matrix element in Eq. (21) over all possible orientations of $\mathbf{R}$ is $(2/3)|\langle r_s\rangle|^2|\langle r_a\rangle|^2$, where $|\langle r\rangle|^2 = |\langle x\rangle|^2 + |\langle y\rangle|^2 + |\langle z\rangle|^2$ so that

$$P_{sa}(dd) = \frac{4\pi e^4}{3hK^2R^6 g_s g_a}\sum_1\sum_2\int dE \times \left\{\int dw_s' p_s'(w_s')|\langle\bar{r}_s\rangle|^2\right\}. \tag{22}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

By using the usual expressions for Einstein's A and B coefficients to evaluate the matrix elements contained here in terms of the experimentally measurable quantities such as oscillator strengths, absorption coefficients, and decay times, Dexter reduces Eq. (22) to the form,

$$P_{sa}(dd)=\frac{3h^4c^4Q_a}{4\pi R^6n^4\tau_s}\left(\frac{\mathcal{E}}{K^{\frac{1}{2}}\mathcal{E}_c}\right)^4\int\frac{f_s(E)F_a[E]}{E^4}, \quad (23)$$

with the absorption data for A and the emission data for S or to the form,

$$P_{sa}(dd)=\frac{3hc^2Q_aQ_s}{4\pi^3n^2R^6}\left(\frac{g_s}{g_s'}\right)\left(\frac{\mathcal{E}}{K^{\frac{1}{2}}\mathcal{E}_c}\right)^4\int\frac{f_s(E)f_a(E)}{E^2}dE, \quad (24)$$

which also contains the emission data for s, where Q_s, Q_a = areas under the absorption bands of S, A; τ_s = decay time for S emission; $\mathcal{E}$ = electric field at an isolated atom; $\mathcal{E}_c$ = electric field within the crystal; K = dielectric constant of the medium; $f_s(E)$ = shape of the observed S-emission band normalized so that $\int f_s(E)dE=1$; $F_a(E)=\sigma_a(E)/Q_a$; $\sigma_a(E)$ = absorption cross section of energy E by A, measurable at low concentrations of A, as the absorption coefficient per unit impurity (A) density in the medium.

This result is similar to Forster's[11] expression for the probability of (d-d) transfer between systems S and A at a distance R_{sa} apart,

$$P_{sa}=\frac{2c}{\pi^4n^2\bar{N}^2\bar{\nu}^2R_{sa}{}^6}\int f_s(\bar{\nu})\rho_a(\bar{\nu})d\bar{\nu}, \quad (25)$$

where $\bar{N}=6.06\times10^{23}$, $\bar{\nu}$ = wave number in cm^{-1}, $f_s(\bar{\nu})$ = molar emission intensity of S at $\bar{\nu}$, $\rho_a(\bar{\nu})$ = molar extinction coefficient of A at $\bar{\nu}$.

The transfer probability thus depends upon the strengths of the individual transitions as determined by decay times, absorption band areas Q, and the energy overlap of the emission and absorption bands of A and S. Neglecting nonradiative transfers in S and transfers from S to S, the following expression for the quantum yield for transfer is obtained,

$$\eta_T=p_{sa}\tau_s/(1+p_{sa}\tau_s). \quad (26)$$

By writing $\beta=(P_{sa}\tau_s)^{\frac{1}{2}}v$, where v is defined as $(4/3)\pi R^3$, one obtains $\eta_T=(\beta^2)/(v^2+\beta^2)$. Let C^+ be the number of density of lattice sites that can accommodate A and let v_0 be the volume excluded by the presence of the sensitizer. Writing $y=x_aC^+\beta$ one finds the average yield as

$$\bar{\eta}_T=y\exp(x_aC^+v_0)\{y^{-1}[\exp(-x_aC^+v_0)-1]+C_i(y)\sin y-S_i(y)\cos y+(\pi/2)\cos y\}, \quad (27)$$

where C_i and S_i are cosine and sine integral functions. For concentrations $x_a\lesssim1\%$ if $C^+=2.26\times10^{22}$ cm^{-3} ($y\lesssim20$); $\beta=8.26\times10^{-20}$ cm^{-3} the factors $\exp\pm(x_aC^+v_0)$ may be set equal to unity and one obtains

$$\bar{\eta}_{T'}=y(C_i(y)\sin y-S_i(y)\cos y+(\pi/2)\cos y\}. \quad (28)$$

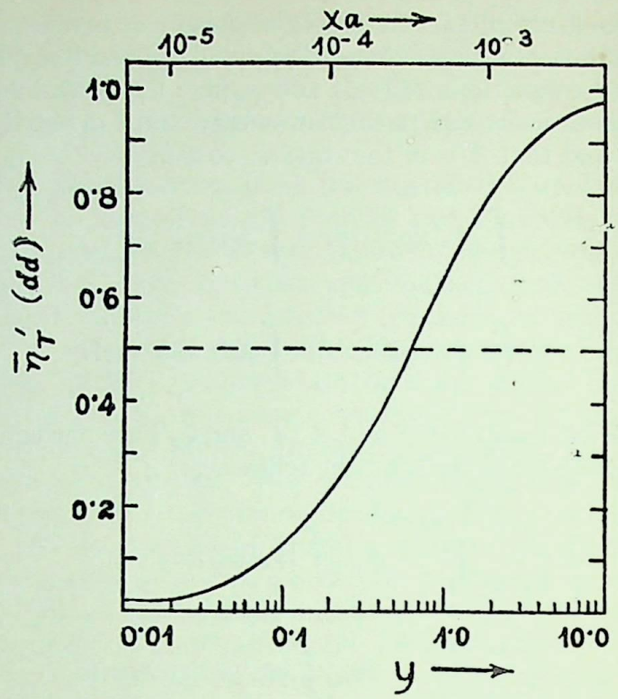

FIG. 1. Quantum yield for dd transfer as a function of the reduced concentration y of the activator. The upper abscissa represents the numerical values of the atomic concentration x_a in the typical case of NaCl crystals (after Dexter).

This function is shown in Fig. 1. For concentrations small enough that $y\ll1$, $\bar{\eta}_{T'}$ varies as $y(\pi/2+y\ln y-0.4228y)$ so that for small x_a, $\bar{\eta}_T$ increases linearly with concentration. For concentrations high enough to make $y\gg1$, $\bar{\eta}_{T'}\to1$.

The temperature dependence of the transfer probability can be understood from Eqs. (23) and (24). Generally Q_a, Q_s, or τ_s are not very dependent on temperature so that the main temperature dependence is determined by the temperature dependence of the energy overlap integral $\int f_s(E)F_a(E)/E^4$. Both f_s and F_a generally possess temperature broadening. In the event of perfect overlapping at all temperatures, the transfer probability decreases with increasing temperature. If, however, the absorption and emission bands have well separated centers, temperature broadening of the bands acts to produce greater overlap, and therefore grater transfer probability. At low temperatures the broadening being negligible as compared to natural zero-point widths, the transfer probability should not depend on temperature.

Electric Dipole-Quadrupole Interaction

When S makes an allowed dipole transition and A a prohibited quadrupole transition to calculate the transfer probability, one can insert in Eq. (19) the absolute square of the matrix element $\langle H_1\rangle$ computed from the second bracket of Eq. (20) and averaged over all

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

orientations of $\bar{R}$. Inserting

$$\langle|\langle H_1\rangle|^2\rangle_{Av}=\frac{9e^4\alpha}{4K^2R^8}|\langle r_s\rangle|^2|\langle N_a\rangle|^2 \quad \text{in Eq. (19),}$$

where $\alpha=1.266$ and $|\langle N_a\rangle|^2=|\langle x_a^2\rangle|^2+|\langle y_a\rangle|^2+|\langle z_a\rangle|^2+2|\langle xy\rangle|^2+2|\langle yz\rangle|^2+2|\langle zx\rangle|^2$ one obtains the following expression for the transfer probability:

$$P_{sa}(dq)=9e^4\pi\alpha/2\hbar K^2R^8g_s'g_a\sum_1\sum_2\int dE \times\left\{\int dw_s'p_s'(w_s')|\langle\bar{r}_s(w_s',w_s'-E)\rangle|^2\right\} \times\left\{\int dw_a p_a(w_a)|\langle N_a(w_a,w_a+E)\rangle|^2\right\}. \quad (29)$$

Relating, as before the bracketed quantities to either emission or absorption data when measurable or significant, for A or S, Dexter obtains

$$P_{sa}(dq)=\frac{135\pi\alpha\hbar^9c^8g_a'}{4\eta^6R^8\tau_s\tau_ag_a}\left(\frac{\mathcal{E}}{K^{\frac{1}{2}}\mathcal{E}_c}\right)^4\int\frac{f_s(E)F_a(E)}{E^8}dE. \quad (30)$$

If τ_s is not measurable or has no significance, one can use the expression

$$P_{sa}(dq)=\frac{135\alpha\hbar^6c^6Q_s}{4\pi n^4R^8\tau_a}\times\frac{g_a'g_s}{g_ag_s'}\left(\frac{\mathcal{E}}{K^{\frac{1}{2}}\mathcal{E}_c}\right)^4\int\frac{f_s(E)F_a(E)}{E^6}. \quad (31)$$

The ratio that $P_{sa}(dq)$ bears to $P_{sa}(dd)$ is calculated from Eqs. (30) and (23) to be $(45\alpha/4\pi^2)(n\lambda/R)^2\tau_a(d)/\tau_a(q)$. Since a quadrupole radiative transition has a probability of the order of $(a/\lambda)^2$ times a dipole radiative transition, one can put $\tau_a(d)/\tau_a(q)$ so that $P_{sa}(dq)$: $P_{sa}(dd)$ is of the order of $(a/R)^2$. Thus, resonance transfer can occur from a sensitizer to a nearby activator having a quadrupole transition in the proper frequency interval whereas direct absorption of radiation by the activator takes place with a probability only $\sim10^{-7}$ of that in an impurity with an allowed transition.

After defining γ by the relation $P_{sa}(dq)=\gamma^{8/3}v^{8/3}\tau_s$ and putting $y=\gamma C^+x_a$, one finds

$$\bar{\eta}_T=y\exp(x_aC^+v_0)\left\{y^{-1}[\exp(-x_aC^+v_0)-1]+\int_0^\alpha(e^{-vt}/1+t^{8/3})dt\right\} \quad (32)$$

and

$$\bar{\eta}_T'=y\int_0^\alpha(e^{-vt}/1+t^{8/3})dt. \quad (33)$$

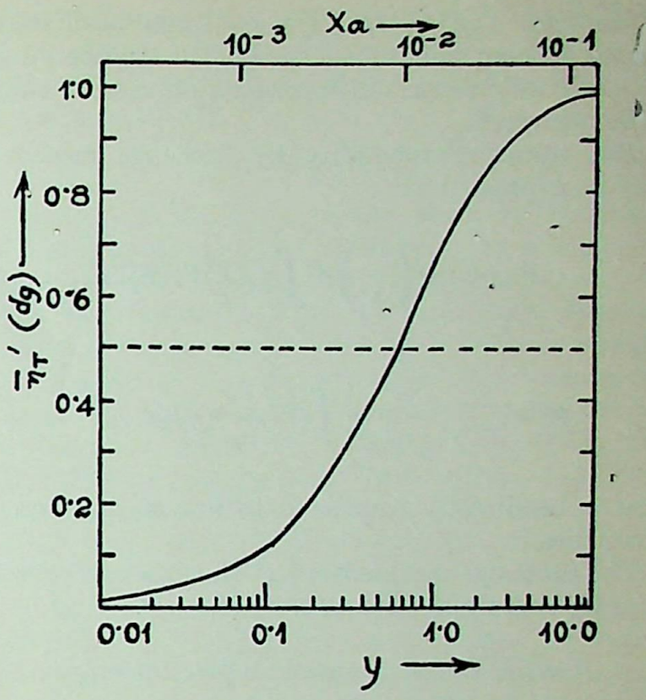

FIG. 2. Quantum yield for dq transfer as a function of the reduced concentration y of the activator, as in Fig. 1. The upper abscissa scale shows atomic concentrations in the typical case of NaCl crystals. The variation of $\bar{\eta}_T'$ with concentration is more rapid in the dq case than in the dd case (after Dexter).

This function is shown in Fig. 2. Since $P_{sa}(dq)$ depends on R more strongly than $P_{sa}(dd)$, $\bar{\eta}_T$ depends upon x_a more rapidly in the dq case than in the dd case.

The function $F_a(E)$ which is the absorption shape function of A cannot be experimentally determined because the absorption would not be observed.

Exchange Effects and Other Forbidden Transitions

Considering only the effects of electron spin, one can write out explicitly the matrix element of H_1 as $\psi(\bar{r},\bar{\sigma})=\varphi(\bar{r})\chi(\sigma)$ where $\chi(\sigma)$ are the spin wave functions.

$$\langle H_1\rangle=\int\varphi_s'^*(\bar{r}_1)\varphi_a^*(\bar{r}_2)H_1\varphi_s(\bar{r}_1)\varphi_a'(\bar{r}_2) \times\chi_s'^*(\bar{\sigma}_1)\chi_a^*(\bar{\sigma}_2)\chi_s(\bar{\sigma}_1)\chi_a'(\bar{\sigma}_2) -\int\varphi_s'^*(\bar{r}_1)\varphi_a^*(r_2)H_1\varphi_a'(\bar{r}_1)\varphi_s(\bar{r}_2) \times\chi_s^*(\bar{\sigma}_1)\chi_a^*(\bar{\sigma}_2)\chi_a'(\bar{\sigma}_1)\chi_s(\bar{\sigma}_2). \quad (34)$$

The first term in $\langle H_1\rangle$ is the Coulomb term treated before, and the second integral is an exchange integral with $H_1=e^2/Kr_{12}$. If the X's are left for the moment the integral can be understood as representing the electrostatic interaction between the two charge clouds

$$Q'(r_1)=\varphi_s'^*(\bar{r}_1)\varphi_a'(\bar{r}_1) \quad \text{and} \quad Q(\bar{r}_2)=\varphi_a^*(\bar{r}_2)\varphi_s(\bar{r}_2).$$

Each function φ dies off exponentially with distance from S or A and each product Q will not be sizeable throughout all space except when r_{12} is small so that

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the integral $\int Q'(\bar{r}_1)(1/r_{12})Q(\bar{r}_2)d\tau_{12}$ may be of sizeable value (R being small) even though the overlap integral $\int Q(\mathbf{r})d\tau$ which enters in normalization, is small enough to be neglected.

The transfer probability by exchange mechanism may be expressed as

$$P_{sa}(ex)=\left(\frac{2\pi}{h}\right)Z^2\int f_s(E)F_a(E)dE, \qquad (35)$$

where

$$Z^2=\sum_1\sum_2\frac{e^4}{g_s{}'g_a\kappa^2}\left|\int Q'(r)\frac{1}{r_{12}}Q(\bar{r}_2)d\tau_{12}\right|^2_{1.2}$$

cannot be directly connected to optical experimental quantities.

The exchange mechanism has an efficiency in energy transfer slightly less than the dq transfer.

Electric Dipole-Magnetic Dipole Interaction

The transfer mechanism arising from an electric dipole-magnetic dipole interaction may be treated by including magnetic fields in the Hamiltonian. The most important in a so-constructed H_1 is $e\hbar/2mc\bar{H}\cdot(\bar{r}_a\times\bar{\nabla}_a+i\bar{\sigma}_a)$, where H is the magnetic intensity at A produced by motion of charge at S. The largest term in H being of the order $(e/c)\bar{R}\times\bar{V}_s/R^3$ or $(e\hbar/mc)\bar{R}\times\bar{\nabla}_s/R^3$. Thus $\langle H_1\rangle$ has the magnitude $(e^2\hbar^2/2m^2c^2R^2)\langle\bar{\nabla}_s\rangle$ or because $\langle\bar{\nabla}_s\rangle=mE\langle\bar{r}_s\rangle/\hbar^2$ one finds

$$|\langle H_1(em)\rangle|^2/|\langle H_1(dd)\rangle|^2\sim(e^2/hc)^4E^2/(e^2/R)^2. \qquad (36)$$

Thus for the nearest neighbors $P_{sa}(em)$ is of the order of 10^{-8} times $P_{sa}(dd)$, small enough to be neglected.

Host Sensitization

Most of the discussion of impurity sensitization applies also to host sensitization, i.e., sensitization of an activator by the lattice itself in which it is embedded. In this case X_s, being equal to unity, is not small enough to forbid S-S transfer. When S has an allowed transition the transfer mechanism from S to S would be a (d-d) process, and depending on the degree of forbiddenness of transitions in A, either a dd process, a competition between dq and exchange or exchange from S to A.

Transference of excitation energy by dipole-dipole interaction should be carefully distinguished from a cascade phenomenon. In the latter process where a photon emitted by S is reabsorbed by A, the quantum yield for transfer depends not only on the concentration (A) but also on the size and shape of the system, as seen from (16).

The quantum yield for transfer by the cascade mechanism can be expressed as follows in terms of the crystal dimension,

$$\bar{\eta}_T(C)=Av\int f_s(E),$$

where A, v, $f_s(E)$, C, and (E) are as defined before and the average is taken over the linear dimension l of the sample. $1-\eta_{0T}$ is the probability that a photon emitted by S will escape from the system and is then equal to η_{cs}. The quantity $C(A)l$ represents the number of impurity molecules A per cm^2 projected on a plane perpendicular to the path of the photon. If we compare a spherical system containing a concentration (A) of A with the same system spread out in a thin film as regards quantum yield, it will be greater in the former case than in the latter, if the transfer takes place by the cascade process whereas it will be independent of the shape and size of the sample if the transfer takes place by dipole-dipole interaction.

(c) Exciton Migration

Exciton or excitation wave, a concept first introduced by Frenkel[13] to mean quick transfer of excitation energy from one constituent to another of a crystal lattice, is a product of the mathematical problem of calculating the excited states of a lattice of interacting atoms or molecules. The physical model used by Frenkel, Peierls,[14] and subsequently, by Slater and Shockley[15] was simple. It consists of a system of identical atoms each containing one electron arranged in simple crystalline array. The electron spin is neglected and both the lowest and the first excited states are assumed to possess no degeneracy. Let atoms be located at the points defined by

$$\mathbf{r}(n)=n_1\tau_1+n_2\tau_2+n_3\tau_3, \qquad (37)$$

where the τ are the primitive translations of the lattice and the n range over all integral values. Let ψ_1 and ψ_2 denote the normal and the excited wave functions of the particular electron at $\mathbf{r}(n)$ and assume that there is so little overlapping of the wave functions on different atoms that the ψ are practically the same as the atomic wave functions. Consequently, ψ_n and $\psi_n{}'$ are orthogonal to each other and to the wave functions of electrons on other atoms. A wave function for the lowest state of the entire crystalline array, which may be expressed as a determinant of the form

$$\psi_0=\frac{1}{(N!)^{\frac{1}{2}}}\begin{vmatrix}\psi_1(\bar{r}_1)&\cdots\psi_1(\bar{r}_N)\\ \psi_N(\bar{r}_1)\cdots\psi_N(\bar{r}_N),\end{vmatrix} \qquad (38)$$

where N is the total number of electrons and atoms. The mean energy of this state is $E_0=\int\psi_0{}^*H\psi_0d\tau$, where H is the Hamiltonian of the entire system.

Let us now consider the wave function ψ_f of the entire system for the state in which one atom is excited from

the state ψ_f to the state ψ_f'

$$\psi_f=\frac{1}{(N!)^{\frac{1}{2}}}\begin{vmatrix}\psi_1(\bar{r}_1)\psi_1(\bar{r}_2) & \cdots\psi_1(\bar{r}_N)\\ \psi_2(\bar{r}_1)\psi_2(\bar{r}_2) & \cdots\psi_2(\bar{r}_N)\\ \cdots\cdots\cdots\cdots & \\ \psi_f(\bar{r}_1)\psi_f(\bar{r}_2) & \cdots\psi_f(\bar{r}_N)\\ \psi_N(\bar{r}_1)\psi_N(\bar{r}_2)\cdots\psi_N(\bar{r}_N). & \end{vmatrix} \tag{39}$$

We cannot regard this system of wave functions as proper representations of the excited states of the crystal because they do not make

$$E_{gf}=\int\psi_g^*H\psi_f d\tau \tag{40}$$

vanish when $m\neq n$.

The N-dimensional matrix constructed from the E_{gf} can be diagonalized by finding those linear combinations ψ' of the ψ_f which are of the form

$$\psi'=\sum a_f\psi_f, \tag{41}$$

where the a_f satisfy the following equation

$$\sum_g a_g E_{gf}=E_{af}'. \tag{42}$$

Since crystal symmetry makes E_{gf} dependent only upon the difference between g and the f values, the N equation (42) can be reduced to the same form if we substitute

$$a_g=a_k e^{2\pi i\mathbf{k}\cdot\mathbf{r}(g)} \tag{43}$$

where $\mathbf{K}$ is a vector in the reciprocal lattice of the crystal. This reduces (42) to

$$E_K'=E_{ff}+\sum E_{f,f+s}e^{2\pi i\mathbf{k}\cdot\mathbf{r}(s)} \tag{44}$$

where $E_{f,f+s}=E_{g+m,g+m+s}$ where m, s are arbitrary integer sets.

After substituting Eq. (44) in (41), we have the normalized wave function

$$\psi_K=\frac{1}{N^{\frac{1}{2}}}\sum e^{2\pi i\mathbf{k}\cdot\mathbf{r}(f)}\psi_f. \tag{45}$$

A wave function of this type represents the fact that the locality where the atom is excited, moves about the lattice with a wave number $\mathbf{k}$. In other words, the excited state is not localized on the particular atom that is excited, but is handed over from one constituent of the lattice to its neighbors.

By virtue of the assumption of weak overlapping we assume that E_{gf} vanishes for all but the nearest neighbors. If E_{gf} has the value ϵ in this case, (44) reduces to

$$E_K'=E_{ff}+\epsilon\sum e^{2\pi i\mathbf{k}\cdot\mathbf{r}}, \tag{46}$$

where $\mathbf{r}$ is to range over the nearest neighbors.

For a cubic lattice with lattice constant a, Eq. (46) takes the simple form

$$E_K'=E_{ff}+\epsilon(\cos 2\pi k_x a+\cos 2\pi k_y a+\cos 2\pi k_z a). \tag{47}$$

This means that the excited levels constitute a band having a spread of the order of magnitude ϵ.

It can be shown that the wave of excitation moves with a group velocity,

$$V=(1/h)\,\mathrm{grad}_K E, \tag{48}$$

and also that it carries no current. We may thus look upon the excitation wave as if it were an uncharged particle created by exciting the crystal and capable of moving about the lattice. This concept is due to Frenkel who called the wave of excitation an exciton.

It is instructive to look into Wannier's[16] model of treating the excitation bands in insulators because of its simplicity. If an electron is removed from the highest filled band of an insulator a positive charge, or positive hole, results. This positive hole may be filled up by an electron from an adjacent lattice constituent, and thus the positive hole may be able to roam about freely in an undistorted lattice. Though the Bloch picture endows the excited electron with freedom of movement independently of the positive hole, one should attract the other with a force that is Coulomb-like at large distances. It has been shown by Wannier that at the discrete levels of the hydrogen atom the excitation bands arise because of the motion of the electron and hole, one about another in closed states, and the different levels in a band behave as if they were different transitional levels of an excited hydrogen atom. This picture allowed Wannier to obtain a set of simple equations from which to derive the wave functions and energy levels of an exciton.

The migration of excitation energy by the exciton method should be carefully distinguished from that by dipole-dipole interaction. When excitons are generated in a crystal, the excitation energy is propagated through the lattice with a given wave-number vector $\mathbf{K}$ and the total wave function of the crystal describes a moving state of excitation energy of previously defined momentum, but indeterminate coordinates. The interaction Hamiltonian which describes the moving state of excitation energy is in form the same as that which determines the probability of transfer in a quantum mechanical collision process. The fundamental difference between them is that the former process is the result of interaction between an excited atom or molecule and all other like units, while the latter process results from interaction between one excited sensitizer and a normal activator. The latter is thus a one-step process which may take place over a distance of many angstroms in a neutral solvent, while the former may be regarded as a stepwise propagation of excitation energy from molecule to molecule covering many successive independent acts and terminates by one of a number of possible events. The motion of an exciton may be terminated by trapping at an impurity, by decay with characteristic emission of the solvent, or by

[16] G. H. Wannier, Phys. Rev. 52, 191 (1937).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

a radiationless transition. The transfer of energy to an impurity by exciton migration obeys a concentration dependence that is entirely different from that in case of the single step process of collision. The theory of exciton propagation in an insulating crystal has been extended by Heller and Marcus[17] to include cases where appreciable overlapping of the electronic wave functions of nearby crystal constituents is absent. Whereas in the primary works of Frenkel, and later Slater and Shockley the ease of exciton propagation was ascribed to the overlap of the excited state wave functions of the neighboring crystal constituents, Heller and Marcus have shown that very good propagation may result, notwithstanding poor overlap, from the coupling produced by the dipole-dipole terms of the interaction Hamiltonian which give rise to the van der Waals interactions in second-order perturbation theory. When one of the lattice constituents is excited to such a state that transition between it and the ground state is associated with a large oscillator strength, the strong coupling between this excited constituent and its identical neighbors in the ground state allows the migration of energy through lattice. This happens because the translational symmetry of the lattice permits of solution of the corresponding Schrödinger equation in the form of moving waves of excitation, analogous to Frenkel's exciton waves. One of their important results is that even in an idealized cubic crystal there exists anisotropy in the propagation of excitons. Two interesting cases of exciton propagation are distinguished, those in which the induced dipole moment $\mathfrak{u}$ is parallel and perpendicular, respectively, to the vector $\mathbf{k}$ of the exciton wave (Fig. 3). Provided there is no interference from polar modes of lattice vibration, exciton waves of the type $\mathfrak{u}\cdot\mathbf{k}=\pi/2$ are excited by absorption of light waves, since in that case the electric vector and the propagation vector for light quanta are normal to each other. Conversion of excitons from the type $\mathfrak{u}\cdot\mathbf{k}=\pi/2$ into the type $\mathfrak{u}\cdot\mathbf{k}=0$ and vice versa may result from scattering collisions with phonons or other imperfections in the lattice. It is of interest to note that the excitons for which $\mathfrak{u}\cdot\mathbf{k}=\pi/2$ have an energy increasing with k for all prominent directions of propagations, namely (100), (110), and (111) in a simple cubic lattice, and thus these excitons created by light waves behave as if they possess a positive mass. Those excitons which are polarized parallel to $\mathbf{k}$ behave in the reverse way and as if they possess a negative mass. The magnitude m' of the effective mass of an exciton is given by

$$m'\simeq mR_0/fn_0a_e,$$

where m is the electronic mass, f is the oscillator strength of the transition between the ground state and the excited state, a_e is the equivalent Bohr radius for the excited atom, and $R_0=(3\pi/4n_0)^{\frac{1}{3}}$, n_0 being the atomic density. Thus, the larger the oscillator strength the quicker is the propagation of radiationless migration of excitation energy from one atom or complex to another atom or complex, attributed by Cario, Franck, and Forser to dipole coupling. The speed of migration varies inversely as the sixth power of their separation. In the case of exciton propagation, by virtue of the very high density of states, the stationary state cannot be located on one particular excited atom at a time and so the appropriate model is much like the electron wave packet in metals, in which collisions changing $\mathfrak{u}$ and $\mathbf{k}$ will take place during the lifetime of the excitations. Following this approach one can think of a typical maximum diffusion distance of an exciton wave packet d as given by

$$d\leq(\langle v^2_{\text{thermal}}\rangle\tau_{\text{thermal}}\tau_{\text{optical}})^{\frac{1}{2}}$$
$$\approx(10^{14}\times10^{-14}\times10^{-8})^{\frac{1}{2}}=10^{-4}\text{ cm.}$$

The total length of the path traversed may be of the order of centimeters. The exciton may be deprived of its energy long before the optical lifetime has expired by a competing process.

All these conclusions are reached on the basis of the assumption of a small amount of overlapping of the excited wave functions of the electrons. In certain ionic and molecular crystals in which the electron wave functions are strong at the widely spaced lattice sites and weak in between, this assumption is an appropriate qualitative description of the state of affairs.

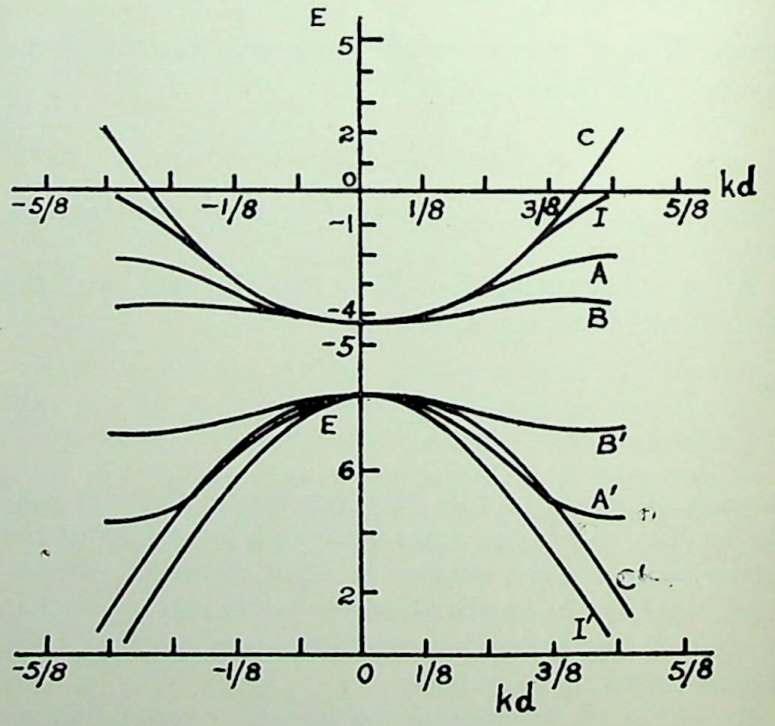

FIG. 3. The energy of exciton waves as a funcion of wave number (after Heller and Marcus). The upper curves refer to excitons for which the electric dipole moment is perpendicular to the direction of propagation, whereas the lower family refers to excitons characterized by polarization parallel to the wave number vector k, d is $(2n_0)^{-\frac{1}{3}}$ where n_0 is the density of ions contributing to the exciton propagation. The energy unit is $\mu_0^2n_0$ where μ_0 is the electric dipole moment of the excited state. Curves A, B, C in the upper diagram and A', B', C' in the lower are for k vectors in the (100), (110), and (111) directions, respectively. Integral approximations in which the excitons behave isotropically are shown in curves I and I'.

(d) Electron and Hole Migration

Production of electrons and holes and their migration were first suggested by Mott and Gurney[18] to account for electronic behavior in insulating crystals. Such a crystal is characterized by a full band of energy levels, named the valence band, separated by a finite energy gap W from an empty conduction band (Fig. 4). If absorption of a quantum of radiation raises an electron to the conduction band, the resulting vacancy in the valence band, called a positive hole, may be filled up by an electron from another constituent whose full band lies above the starting band of the absorption processes in Fig. 5(a) and thus may be caught in a trap. When the free electron from the conduction band finally recombines with its holes trapped in the new host, there results a new emission. It may also happen that the excited electron temporarily falls into an intermediate vacant band below the conduction band as in Fig. 5(b) and the holes become mobile through the lattice until it recombines with its trapped counterpart with the emission of a new band. The energy set free by the trapping of the electron or its hole may be emitted as infrared radiation or dissipated as heat. The traps of the electrons or holes are localized—the energy levels being produced by an activator or lattice flaws, or cracks. Such crystals exhibit photoconductivity because of the mobility of an electron in the conduction band or because of its positive holes in the valence band.

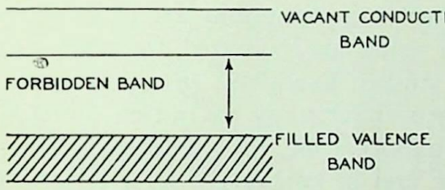

FIG. 4. Schematic representation of the filled and unfilled levels.

When energy transfer takes place over a long distance, each of these processes requires a transport mechanism:

(1) In a quantum mechanical collision process, the collision partners themselves may become vehicles of long distance transportation of energy.

(2) The excitation energy may travel through the lattice by the migration of an excited electron and its holes freed from each other.

(3) In the exciton mechanism, the transport of energy through the lattice takes place in the shape of excitation wave.

(4) Photon absorption is not a localized process but may occur over larger distances.

Although the same mechanism may account for energy transport and its transfer such as in CaWo—Sm (mechanism 3) and the Zn—S luminiphors (mechanism 2), this is not indispensable. It is not improbable that

[18] N. F. Mott and R. W. Gurney, *Electronic Process in Ionic Crystals* (Oxford University Press, New York, 1949).

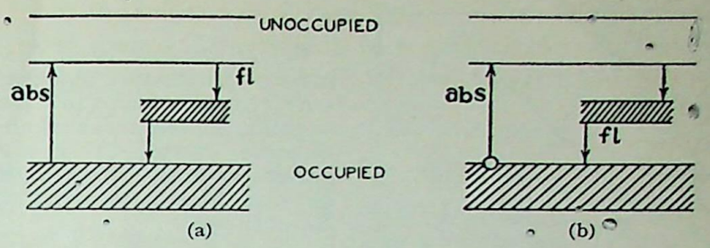

FIG. 5. The excited electron falls into an intermediate vacant band below the conduction band.

excitation energy is transported by say migration of electrons and holes, whereas the final transfer is effected by, say, a collision process.

2. FLUORESCENCE TRANSFER IN ORGANIC MIXED CRYSTALS

In 1949 Franck and Livingston[9] summarized the facts on fluorescence in organic mixed crystals brilliantly. Since then many more publications have appeared and considerable new results are now at hand, so it seems desirable to discuss the subject afresh. The present discussion is confined to organic crystals in general and naphthacene in anthracene in particular for the following reasons: (a) a considerable amount of experimental results and theoretical discussion have been published on it which have made it a matter of controversy; (b) we are studying the matter in this laboratory and some interesting quantitative results have been obtained by us and our collaborators.

(a) Exciton and Absorption

Interest in transfer of energy from one molecule to another in an aromatic solid seems to grow continuously from the anthracene-naphthacene problem. Many workers[19–22] have observed that in the pure crystalline state naphthacene hardly fluoresces, whereas dissolved in solid anthracene or chrysene, it fluoresces brilliantly with its characteristic yellow-green color and the quenching of host crystal fluorescence. The quantum yield of its photofluorescence increases from 0.04 in a pure crystal to about 1 in anthracene.[23] Bowen[20] suggested that the mechanism of transfer of excitation energy from anthracene to naphthacene molecules embedded in the anthracene lattice possesses a close resemblance to that observed in a typical inorganic phosphor, and that the energy of excitation travels by the exciton mass. On the other hand, Ganguly's[24] investigations into the absorption and fluorescence phenomena of these aromatic hydrocarbons under different physical conditions, particularly the depend-

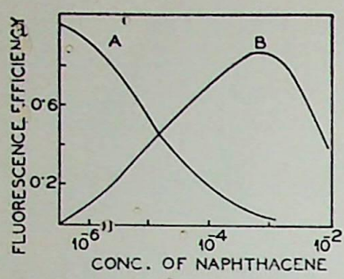

FIG. 6. Dependence of fluorescence efficiency of naphthacene concentration in the naphthacene contaminated anthracene crystal. *A* is for anthracene fluorescence, *B* is for naphthacene fluoroescence (after Bowen).

ence of the latter upon the wavelength of exciting radiation suggests that the exciton mechanism is unnecessary in this case and that the enhanced fluorescence of naphthacene could be related to the excitation of the naphthacene molecules by way of absorption of the exciting radiations as well as the fluorescent light of anthracene. This suggestion was based on the following observations:

(i) When excited by light of wavelength from 4030 to 4350 A, green anthracene crystal or a green chrysene crystal emits the characteristic naphthacene fluorescence, except that it is shifted toward the red due to the solvent effect. Naphthacene molecules absorb these exciting wavelengths but the anthracene lattice does not.

(ii) Since the absorption region of naphthacene overlaps the emission region of anthracene (3650 to 5000 A), the naphthacene molecules absorb not merely the exciting radiation 3650, but must also absorb the fluorescence radiations of anthracene.[22]

(iii) There is positive evidence for photon absorption by naphthacene molecules followed by photon emission, and lack of evidence for the exciton mechanism.

Almost simultaneously Bowen and his co-workers[25–28] were investigating the effect of naphthacene concentrations, particle size etc., on the intensities of anthracene and naphthacene fluorescence. They observed the following.

(i) At a concentration of 10^{-5} naphthacene molecule per anthracene molecule, the green naphthacene fluorescence is visible and at 10^{-4} naphthacene molecules per anthracene molecule it grew strong. Lack of molecular proximity and orientation in liquid solution inhibited the transfer so that a green crystal of anthracene with a low concentration of naphthacene when dissolved in benzene did not give the characteristic green fluorescence of naphthacene under the same excitation.

(ii) The curves (Fig. 6) relating the intensities of anthracene and naphthacene fluorescence to the concentration of naphthacene in an anthracene crystal could be represented by $n=1/1+kx$ and $1-\eta=kx/1+kx$, where n=quantum efficiency of fluorescence of host lattice; $k=a$ constant for a pair of compounds in the host and guest relation, excited by a particular radiation; and x=guest concentration in g per g of the host. For solid solutions of anthracene in naphthalene k was found to be 5×10^4 when excited by 2900 to 3200 A radiations at 20°C, for naphthacene in anthracene crystal excited by 2900 to 3200 A, k was found to be 2×10^5 at 20°C.

(iii) The curves of intensities of fluorescence *vs* naphthacene concentrations in anthracene crystal do not differ greatly from those in solutions precipitated from one solution. When separate mixtures of the two are taken, there is produced a great difference.

(iv) The intensity ratio of the 0—1 and 0—2 bands in the fluorescence of anthracene remains unaltered for all concentrations of naphthacene in anthracene crystals.

(v) The intensity of the 0—1 band compared to that of the 0—2 band in the fluorescence of anthracene increases as the particle size is diminished and finally approaches that for dilute solution in benzene.

These observations were regarded by Bowen and his co-workers as evidence supporting the exciton mechanism in these crystals. Later it was shown by Birks[7] that the observations (i) and (ii) could not lead to this unambiguous conclusion.

Lipsett and Dekker's[29] investigtions are of interest in that, apart from using an improved technique of measurement, they studied band-wise the spectral intensity of fluorescence under x-ray excitation emitted by solid solutions of naphthacene, 1,2,5,6-dibenzanthracene in naphthalene and in anthracene as a function of concentration. The relative band intensity of impurity fluorescence increased with the rise of concentrations in the host lattice, reached its maximum, and then fell off in a manner shown in Fig. 7, for 1,2,5,6-dibenzathracene in naphthalene. Considering the high efficiencies of energy transfer at concentrations as low as 1.01×10^{-4} mole naphthacene per mole naphthalene and 2.93×10^{-4} mole naphthacene per mole anthracene

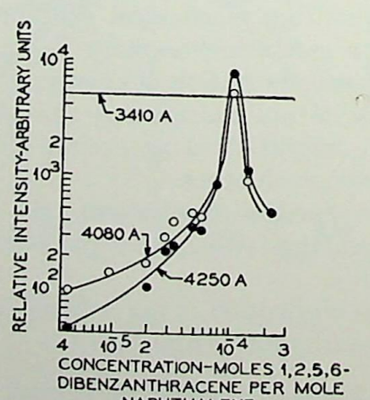

FIG. 7. Intensity of the 4080 and 4250 A bands of 1,2,5,6-dibenzanthracene fluorescence relative to the 3410 naphthalene fluorescence band as function of concentration (after Lipsett and Dekker).

for maximum transfer, they discard the absorption and re-emission as unlikely and regarded the exciton mechanism as more probable. Subsequently, they observed that the intensity of fluorescence under x-ray excitation of anthracene molecules embedded in the naphthalene lattice increased steadily with concentration even after the naphthalene fluorescence was quenched. They attributed this complex behavior to a vigorous fluorescence of anthracene molecules by themselves in addition to the transferred excitation energy from naphthalene molecules to anthracene molecules by way of exciton. The anthracene bands at 3505 and 3700 A arose primarily from the transferred excitation energy and those at 3895, 4200 A, etc., from a combination of transferred excitation energy and molecular fluorescence.

Recent investigations of fluorescence of solid solutions of nine aromatic hydrocarbons in anthracene and pyrene by Northrop and Simpson[30] have supplied significant quantitative information as regards the transfer of excitation energy from solvent to solute molecule. The degree of energy transfer is discussed in terms of two experimentally determined quantities, namely, the quenching factor and the transfer efficiency, defined by

$$Q=(S-S')/S \quad \text{and} \quad T=I/(S-S'),$$

where S = integrated emission of pure solvent molecules, S' = integrated emission of a pure solvent containing solute molecules, and I = integrated emission of solute molecules. These investigators found (Fig. 8) that for anthanthrene dissolved in anthracene the quenching factor is proportional to concentration up to 10^{-2} M and at higher concentration becomes less than what is expected from the proportionality relation. The behavior of transfer efficiency with increasing concentration C is given in Table II. Thus all the quanta quenched in anthracene fluorescence do not reappear as anthranthrene fluorescence. There is an optimum concentration, 10^{-3} M in this case, at which T is maximum, unity in this case. For molecules of smaller size studied by them such as naphthacene, pentacene, perylene, etc., T was greater at 10^{-3} M than at 10^{-4} M. Larger molecules such as iso-violanthrene and ovalene display a reversed tendency. The concentration dependence of Q is semi-quantitatively explained by Northrop and Simpson on the basis of exciton migration. When the matrix lattice of the solvent is not contaminated with impurity molecules a solvent molecule may return to the ground state by emitting fluorescence, by nonradiative transitions causing internal quenching, or by transferring its excitation energy to a like neighbor and let α, β, and γ be the probabilities per unit time of the individual processes, respectively. Considering that an exciton continues to move through the crystal until it ends its life it is potentially able to cause fluorescence, they obtained the total probability of emission of one fluorescence quantum per one molecule initially excited as $S=\alpha/(\alpha+\beta)$ where the matrix lattice contains foreign molecules of concentration c, there is a probability, q, say, that the exciton may be captured during its propagation by an adjacent foreign molecule. This reduces the probability of emission by a solvent molecule to

$$S'=\alpha/\alpha+\beta+\gamma cq,$$

where s and s' are proportional to S and S'. Therefore,

$$Q=\frac{S-S'}{S}=\frac{s-s'}{s}=\frac{\gamma cq}{\alpha+\beta},$$

which predicts that Q is proportional to c in agreement with the experimental results.

The investigations of Northrop and Simpson point out that there is no correlation between quenching and the overlap between solvent emission and impurity emission and impurity absorption. There is very little overlap in the case of iso-violanthrene embedded in the anthracene lattice and yet iso-violanthrene quenches anthracene fluorescence strongly with $Q=11$ and 31 at $C=10^{-4}$ and 10^{-3} M, respectively. Naphthacene has a very strong absorption overlapping the emission of pyrene but there was observed no quenching or transfer when at high concentration. These facts are of great importance as they rule out the possibility of energy transfer by collision processes. The probability of energy by collision is proportional to $\int \nu^{-4}E(\nu)A(\nu)d\nu$, where $E(\nu)$, $A(\nu)$ are the fluorescence spectrum of the excited molecule and the absorption spectrum of the acceptor molecule.

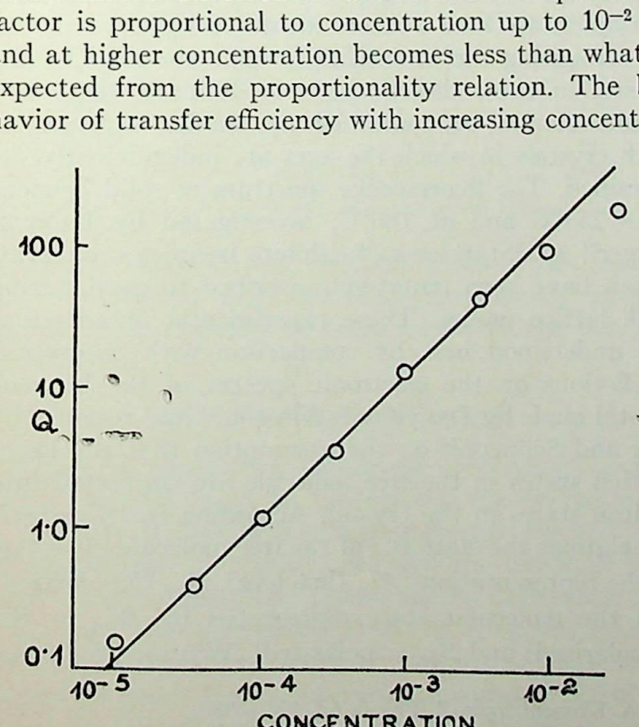

FIG. 8. Dependence of the quenching factor Q on the concentration of impurity (after Northrop and Simpson).

3. ELECTRONIC STATES OF AROMATIC CRYSTALS

One of the glaring features of early investigations of energy transfer is that the question whether transference of excitation energy by way of the exciton in aromatic crystals is feasible in view of weak intermolecular binding in them, was not attacked by a consideration of the nature of electronic states in these crystals. In spite of the works of Heller and Marcus,[17] some[7,9] had the idea that exciton propagation required strong intermolecular coupling. As there existed at that time little evidence of such intermolecular coupling in these crystals, often the possibility of exciton propagation was ruled out.

Theoretical works on the electronic states of molecular crystals, begun not long ago, are all based on the elementary theory of excited states of a lattice of interacting atoms or molecules given by Frenkel,[13] later by Slater and Shockley[15]; and improved by Peierls[14] to include the effect of lattice vibrations. One of the principal results of this theory is that in aromatic hydrocarbon crystals beneath conduction bands there occur nonconducting excited states called exciton bands. Just as the conduction bands are analogous to ionization levels of atoms or molecules, these excitation bands in a crystals are analogous to the excited states of free atoms or molecules and are characterized by the fact that the optical excitation to these bands is accompanied by propagation of this state of excitation from one lattice constituent to another, by what is called an "exciton."

Nonconducting excited states or exciton states as they are generally called, arise in two ways. In weakly bound solids (molecular crystals such as anthracene, etc.), the exciton bands correspond closely to the lowest excited states of the constituent atoms or molecules in the free state. Secondly, the strongly bound ionic or covalent crystals, where the constituents have lost their individuality, arising in the ionic case from the removal of an electron from one atom to a neighbor, or by the sharing of electrons with neighbors in the covalent case. An application of Frenkel's exciton theory to the calculation of energy states of molecular crystals was made first by Davydov.[31] He envisaged a weak coupling model of a molecular crystal characterized by an intermolecular interaction energy small compared to the intramolecular energy so that crystallization does not appreciably affect the electronic structure of a molecule. This is required by the fact that the broad features of the visible and ultraviolet spectra are but little changed by the process of crystallization. One of the most significant results reached by his calculations is that from each excited level of a free molecule there originates a band of energy levels in the crystal. And what is more important, corresponding to a transition in the free molecule there may take place several optical transitions in the crystal, notwithstanding the nondegeneracy of the free molecular levels. This results in multiplicity of lines corresponding to one optical transition in the free molecule. This effect, called Davydov splitting, must be carefully distinguished from the two other well-known effects of crystal field. One of these is the splitting of levels that are degenerate in the free molecule by the crystal field. This effect has been discussed by Bethe. It has found wide application in the interpretation of the spectra of rare earth crystals. The other is the occurrence of crystal-field-induced transitions which are altogether forbidden in the free molecules.

We now discuss the extent to which the exciton effects occur in the crystals of aromatic hydrocarbons in accordance with theoretical predictions.

(a) Benzene Crystal

The benzene crystal being the simplest of the aromatic crystals, its importance in interpreting the nature of the solid state of the aromatic hydrocarbons is unique. The electronic spectra have been investigated both experimentally and theoretically. The first transition in solid benzene was first observed by Kronenberger.[32] The spectrum exhibited some degree of fine structure not accountable without assuming some crystal effects, either Davydov splitting, or combination with lattice modes. Recently Broude *et al.*[33] have investigated the absorption spectrum of single crystals of benzene using polarized light and detected two perpendicularly polarized lines, separated by 25 cm^{-1} and corresponding to the lowest excited singlet state of the free molecule. Inasmuch as these workers identified the crystal axes by comparing the intensities of light absorbed by the crystal in these directions, it is desirable that their results should be confirmed by similar experiments with crystals in which the axes are independently determined. The fluorescence spectrum of solid benzene at −253°C and at 180°C, investigated by Kronenberger[32] and Starkiewicz[34] exhibits frequency intervals which have been tentatively ascribed to combination with lattice modes. These experimental observations are understood best by comparison with theoretical predictions on the electronic spectra of the benzene crystal made by Davydov,[31] Winston,[35] and recently by Fox and Schnepp[36] on the assumption that the lower excited states in the free molecule are converted into exciton states in the crystal. According to Davydov's calculations the state B_{1u} of the free molecule gives rise to the representations A_{1u} (inactive), B_{2u} (b polarized) and the molecular state represented by B_{2u} to B_{1u} (a polarized) and B_{3u} (c polarized). Winston confirmed

these results and also found that the forbidden 0—0 transition of the free molecule is not prohibited in the crystal. Fox and Schnepp calculated the exciton band energies and band widths in the benzene crystal corresponding to the B_{1u} and the B_{2u} states of the free molecule, to which dipole transitions from the ground state are allowed. They used the x-ray determination of the benzene crystal structure made by Cox and Smith,[37] more recent, and exciton wave functions, more general, than those used by Davydov. Their results are tabulated in Tables III and IV for exciton functions constructed from molecular states of symmetry B_{1u} and B_{2u}. The foregoing results belie our expectation of identifying the B_{1u} and B_{2u} band from polarization measurement because in each band the transitions are a, b, and c polarized in the same order of energy. The band widths are 720 and 58 cm^{-1}. The two optically active levels observed by Broude *et al.* with a separation

of 25 cm^{-1} confirm the splitting qualitatively though not qualitatively and thus lend experimental support to the exciton nature of these bands in the benzene crystal.

(b) Naphthalene Crystal

Quantum mechanical treatment of the naphthalene crystal on the basis of the exciton theory has been carried out by Davydov and more recently by McClure and Schnepp.[38] The results are that the free molecular energy levels are split by crystal forces, each into α and β components such that transitions from the ground state to them are perpendicularly polarized. The exciton theory intensity figures for these transitions in terms of free molecular intensity are given in Table V.

The a- and b-axis polarized absorption spectra of

TABLE V.

single crystals of naphthalene were investigated by Prikhotjko,[39] Craig and Lyons,[40] and more recently by McClure and Schnepp. The latter workers made an attempt to interpret the observed structure of the a- and b-polarized spectra at 20, 77, and 298°K using single crystals of naphthalene of thickness 10 mm to 0.5 μ. Table VI depicts the observed effects of crystallization on the electronic transitions to the upper states in a naphthalene molecule. They are displacement and dichroic splitting of the 0—0 band in both transitions. The observed polarization behavior of the crystal absorption is described and compared with the exciton theory predictions in Table VII.

The fluorescence spectrum of the naphthalene crystal at 20°K, investigated in great detail by Obreimow and Sabaldas[41] and more recently by McClure and Schnepp, is polarized along the a and b axes of the crystal. Factor group splitting of vibrational level absent in the mixed crystal is evident in the doubling of the line 1384 cm^{-1} in the one and two vibrational quanta and of some

combination lines involving 1384 cm^{-1} in the pure crystal. Measurements on the 1348 series are entered in Table VIII.

Thus the gross features of the absorption and the fluorescence spectra satisfy the predictions of the exciton theory for molecular crystals.

(c) Anthracene Crystal

The energy levels of the anthracene crystal were first treated by Davydov as an application of his theory of light absorption in molecular crystals. The absorption spectrum has been investigated by Obreimov and Prikhotjko[42] at 20°K, by Craig and Hobbins,[43] Lyons,[44] and Sidman.[45] The fluorescence spectrum has been studied by Obreimov, Prikhotjko, and Sabaldas[46] at 20°K, Pesteil and Barbaron[47] at 14°K, and Sidman[48] at 4°K. Craig and Hobbins, following Davydov, calculated the splitting, shift, and polarization ratio associated with an electronic transition in the anthracene crystal. Davydov's theory predicts that the second absorption system of anthracene will be split in the crystal by 16 000 cm^{-1} if it were due to a long axis transition and by 1000 cm^{-1}, if due to a short axis transition. Craig and Hobbins investigated the a- and b-polarized absorption spectra of the crystal and observed that the peak of the b spectrum in the second system occurred at 2680 A so that for $A_g - B_{3u}$ (long axis) assignment, the peak of the a spectrum should fall at 1900 A. Though they could not detect it, they observed a continuous rise of absorption until the spectrum was cut off at 2300 A in a crystal of thickness 0.1 μ so that the peak was expected beyond 2300 A. Recently, Lyons[44] reported that experiments with polarized light in the vacuum ultraviolet located the split components at 2200 A and at 1890 a.u. and the absorption is greater perpendicular to the b axis than parallel to it. This allows one to interpret the 1890 a.u. absorption as the a component of the vapor $A_g - B_{3u}$ transition polarized along the long molecular axis.

On the basis of the exciton theory, Craig and Hobbins calculated by first-order perturbation the polarization ratio of the a-b polarized spectrum in the second system and obtained theoretically molar extinction coefficients in the crystal from the solution values. The predicted value was 9100±500 for the b-crystal absorption, taking the solution extinction coefficient as 232 000 while the experimental value obtained by Bree and Lyons[47] was 9450. The polarization ratio ($I_b : I_a$) 1.8:1, observed by Craig and Hobbins for the first absorption system in anthracene, later confirmed by Ganguly *et al.*,[49] was quantitatively interpreted by Craig on the basis of exciton theory modified by crystal-induced mixing of two excited electronic states to be due to $A_g - B_{2u}$. This interpretation leads to a value 21 000 of molar extinction coefficient while the experimental value is 22 800 as measured by Bree and Lyons.

Thus, the observed behavior of electronic transition in the anthracene crystal confirms the predictions of the exciton theory. Calculations of Craig and Hobbins were made by considering the dipole-dipole interaction between molecules not more than 20 A apart. Craig showed that the influence of distant molecules made no difference in their calculated results because the interaction summation converges within a distance of 20 A in the anthracene crystal. Fox and Yatsiv[50] also critically discussed the dependence of the calculated splitting and shift on the shape, size, and direction of propagation of the exciton wave packet. They found that the observed splitting could not lead to an unambiguous long axis assignment for the second absorption system since by reasonable assumptions as to the shape and size of exciton wave packet, one may interpret the observed splitting on the basis of a short axis assignment while by these assumptions one may interpret the observed frequency shift as confirming long axis assignment.

The long wavelength absorption and fluorescence have been investigated in greater detail in the ab plane at 4°K by Sidman.[45] The absorption spectrum is found to consist of at least two regions, one which extends from 25 400 to 30 000 cm^{-1} in both the a- and b-polarized spectra and the other which extends downward from 2540 to 3000 cm^{-1} and appears only in the b polarization. The former, which consists of strong, broad absorption bands, the first band peak being located at 25 400±20 cm^{-1} by Sidman, at 25 380 cm^{-1} by Obreimov and Prikhotjko,[51] and at 25 350 cm^{-1} by Craig and Hobbins, as electronic vibrational transition to the two transitionally allowed levels of the free exciton band derived principally from L_a, B_{2u} state of an

anthracene molecule. The latter regions which consist of many weak bands and lines such as at 24 809, 24 836, and 24 989 cm^{-1} detected by Sidman is assigned by Sidman to transitions from the ground electronic state to the trapped exciton states of the crystal, predicted by Frenkel[12] and Davydov.[52] In addition to the phenomenon of propagation of a free exciton, Frenkel considered the case where the crystal lattice may suffer distortion in the neighborhood of a migrating exciton. His result is that the exciton may be trapped at the site of the local distortion produced by it, if the energy of the trapped exciton is less than that of the free exciton. The low intensity of absorption in this region is caused by a nonvertical Franck-Condon transition of the lattice, since the orientation of the molecule in the lattice is different in the upper and lower electronic states.

The fluorescence spectrum as observed by Sidman at 4°K consists of broad bands superimposed with sharp structures. The fluorescence spectrum has several origins, principally below 24 975 cm^{-1}, which do not coincide with the origin of strong absorption at 25 400 cm^{-1}. This gap of several hundred cm^{-1} between the origins of fluorescence and absorption has been verified by all workers and is significant. It shows that radiationless transference of excitation energy from free exciton levels to trapped exciton levels is rapid so that no fluorescence takes place from the free exciton levels at 25 400 cm^{-1}. This gap between the origins of absorption and fluorescence has been found to exist in crystalline naphthalene and phenanthrene and is similarly accounted on the basis of the trapped exciton theory of Frenkel. Sidman also points out that calculations of Craig[13] applied to Frenkel's prediction show that the relative shift of electronic transition in vapor mixed and pure crystals can be interpreted as a semiqualitative proof of the existence of trapped exciton.

(d) Naphthacene Crystal

The first absorption system of tetracene single crystals under light polarized parallel and perpendicular to the b axis of the crystal was investigated by Achis.[53] The maxima in one spectrum are displaced from those in other, so that Davydov splitting is compared. There seems to be no published absorption data on the second and third systems. Bree and Lyons[54] recently investigated the polarized ultraviolet spectrum of tetracene single crystals by the photoconductance method and confirmed splitting in the first absorption system as shown in Fig. 14. The flatness of the photoconductance curve in the second and the third absorption system does not give any information about splitting there. The absorption and photoconductance of the first system are entered in Table IX. Recently, the absorption and fluorescence spectra of tetracene in solid substitutional solutions at 20°K have been investigated by Sidman.[55] The lowest excited singlet state at 20 246 cm^{-1} has been found to be B_{2u}, L_a since the transition with the ground state is polarized along the short axis of the molecule.

(e) Phenanthrene Crystal

The a- and b-polarized absorption and fluorescence spectra of single crystal of phenanthrene have been investigated at 20°K by McClure.[56] The absorption spectra show that the strong a-polarized 28 613 cm^{-1} band and the strong b-polarized 28 660 cm^{-1} band act as if they are the two components of the 0—0 band split by intermolecular resonance. The former belongs to the B_u representation and the latter to the A_u representation of the factor group C_{2h} of the crystal so that the factor group splitting is 47 cm^{-1}. The vibrational frequency 1378 cm^{-1}, a C—C stretching mode also becomes split into 1370 and 1386 in the crystal. The total width of the exciton band is 280 cm^{-1}, the band beginning at 28 540 cm^{-1} and terminating at 28 820 cm^{-1}.

The weak absorption bands at 28 315 and 28 408 cm^{-1} on the red side of the 0—0 band are not regarded by McClure as a part of exciton band. Similar bands also occur in the crystals of anthracene and stilbene as observed by Sidman. The fluorescence originates at or near the weak absorption band at 28 315 cm^{-1}. Sidman has recently interpreted these low lying emitting levels as the trapped exciton bands of Frenkel.

(f) Hexamethyl Benzene Crystal

The molecular plane in the hexamethyl benzene crystal lies almost parallel to the ab plane of the crystal, the b axis of the crystal being in the plane of the benzene ring. The absorption spectra of the hexamethyl crystal under polarized light were investigated by Scheib *et al.*[57(a)] They concluded that the polarized light absorption in the near ultraviolet takes place predominantly

in the plane of the benzene ring; though they report a definite absorption perpendicular to the ring planes, amounting to about ten percent of parallel absorption at room temperature. A detailed investigation of the absorption parallel and perpendicular to the ring plane was recently made by Schnepp and McClure[57(b)] at high resolution at 20°K in the 2800 A region. The hexamethyl benzene crystal contains one molecule per unit cell and because the excitation exchange energy between the neighboring molecules should be small, one can expect that the spectrum should be free from all the complications resulting from the presence of two or more molecules per unit cell and that the spectrum exhibits molecular properties and not crystal properties. The analysis shows that the 0—0 transition placed at 35 136 cm^{-1} is much stronger under light polarized perpendicular to the benzene ring than under light polarized in the plane. The in-plane absorption is due to a forbidden transition. Detailed quantum mechanical calculations show that the observed behavior, of the 0—0 band under polarized light is caused not by crystal effects but by the destruction of molecular symmetry by the unsymmetrical positions of the methyl groups in the S_6 structure. This distortion gives rise to weak perturbation of the π electron state by the perpendicular non-π electron states.

The fluorescence spectra, investigated by Schnepp and McClure at medium resolution, exhibit polarization of bands but not as complete as in absorption. As the 0—0 band, calculated from the fluorescence spectrum by use of Raman frequency, is located at 35 140±8 cm^{-1}, it is concluded that both absorption and fluorescence originate from 35 136 cm^{-1}. If this is so, then the crystalline band in this crystal must be either very narrow or the allowed level of the band must lie very near the bottom of the band.

Thus nonconducting excited states or exciton states do occur in most of the insulating aromatic crystals investigated as a result of excitation in the fundamental absorption band. The excited regions—called excitons—are believed to be mobile and capable of transporting energy through a crystal. The existing experimental evidence for exciton migration in these crystals rests mainly on indirect observations.

The work of Apker and Taft,[58,59] shows that excitons are able to create and destroy F centers. Exciton migration has been shown by Northrop and Simpson[30] to account quantitatively for the fluorescence quenching of aromatic hydrocarbons containing impurities; Sidman[45] has presented evidence derived from differences in the absorption and fluorescence spectra of anthracene which implies that excitons can be trapped at lattice imperfections. All these experiments depend on the interaction of excitons with particular centers of the lattice. That there occurs actual migration of excitons through the anthracene lattice has been recently demonstrated by the investigation of Simpson.[60] He devised a method which enabled him to measure the exciton motion directly. The observed diffusion length in the case of anthracene is found to be 460 A. In an isotropic medium this would correspond to a root-mean-square displacement of 1120 A between the points of origin and decay of an exciton.

Dexter[61] points out that a phosphor containing luminescence centers can be used as a detector of excitons. Thus it is possible to detect the diffusion of excitons from an activator free crystal into a contiguous crystal, if the latter contains centers capable of trapping the excitons. One surface of a thin specimen is covered by an exciton detector, the opposite face of the specimen is illuminated in the fundamental absorption band. The luminescence emitted by the detector is drived partly from excitation by that fraction of the primary radiation not absorbed in the specimen and partly from excitons originating in the specimen. A separate measurement of the transmission of the specimen suffices to separate the two contributions; hence to determine the flux of excitons into the detector.

The allowance for reabsorption of anthracene fluorescence by naphthacene, was found by measuring the emission from specimens which were made with the anthracene and detector deposited on separate glass plates, and then put together with a small air gap between. In this arrangement transfer by exciton diffusion was suppressed.

4. INFLUENCE OF CRYSTAL SIZE ON THE SPECTRAL NATURE AND DECAY TIME OF FLUORESCENCE

Though the matters discussed in the previous section bear testimony to the exciton nature of the electronic bands and to the migration of excitation energy by way of excitons, some experimental facts give evidence of energy migration by photon reabsorption. In this case efficiency of fluorescence escape from aromatic crystals shows a dependence upon crystal size, in contradiction with predictions of exciton theory.

The long-known fact that overlap of emission and absorption spectra of a system is apt to alter the spectral character of fluorescence due to self-absorption and re-emission, is given proper consideration in the case of organic crystals by the investigations of Kortum and Finckh,[62] Bowen and Lawley,[63] and Little and Birks.[64] They show that the transmitted photofluorescence spectrum of an organic crystal is critically influenced by crystal thickness. That this fact cannot be ignored is evident from the fluorescence spectrograms of anthra-

cene, *trans*-stilbene, *para*-terphenyl, and diphenylacetylene for thick crystals recorded by Koski,[65] Koski and Thomas,[66] and Sangster.[67]

Birks and Little[68] studied the spectral change in the fluorescence of each of these compounds as they changed the fluorescent specimen from single crystals of 1-cm thickness to microcrystalline layers deposited on a thin glass plate by evaporation of a dilute solution of the compound in xylene and the mode of observation from transmission to reflection. The fluorescence spectrum of anthracene (Fig. 9) gets extended into the ultraviolet as far as 3700 A and about 80% of this primary fluorescence suffers reabsorption in a one centimeter thick crystal. These observations were carefully re-examined by Birks and Wright[69], who used improved technique and made relative quantum intensity measurements on one centimeter thick crystal specimens and very thin microcrystalline layers deposited on quartz plates. They observed that the microcrystalline fluorescence spectrum corresponds to the complete molecular emission; 76% of the primary molecular emission from a 1-cm thick anthracene crystal could not escape reabsorption so that the probability of escape of molecular fluorescence, K was 24. In a thick *trans*-stilbene crystal 40% of the molecular fluorescdnce was reabsorbed.

These investigations lend support to the photon cascade theory formulated by Birks[70] and later on supported by Fowler and Roos.[71] Based on the fact that the absorption coefficient of an organic crystal is high, exceeding 10^3 in the first absorption band system of anthracene, and that there is overlap between the emission and absorption spectra, this theory proposes that in a thick crystal, the part of the primary molecular fluorescence which is emitted in the region of absorption is practically reabsorbed in a path length of a few wavelengths. This reabsorbed radiation is re-emitted as fluorescence, a fraction of which is again absorbed by succeeding layers, these processes of absorption and emission following each other until all the excitation energy either escapes from the crystal or is dissipated thermally by internal conversion. Thus the intermolecular energy transfer takes place by expansion of the excitation column, not by the mechanism of exciton migration but by the absorption and reabsorption of the primary fluorescence. This is an extension of Ganguly's[22] theory of transfer of energy from the anthracene lattice to the naphthacene molecules embedded in it through absorption of anthracene fluorescence by naphthacene molecules. But our recent measurement on the coefficient of absorption of naphthacene shows that the probability of naphthacene excitation by absorption of fluorescence of anthracene is remote.

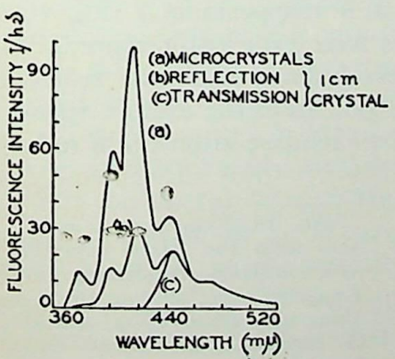

FIG. 9. Anthracene fluorescence spectra excited by 2537 A (after Birks and Wright).

The photon cascade theory seems to be strengthened by surprisingly few existing photofluorescence decay time measurements of organic crystals. Liebson[72] found that for anthracene the photofluorescence decay time t_f changed from 2.0±0.5 mμsec for a ½% solution in benzene to 17 mμsec, for a crystal. For terphenyl it is increased from 2.5±0.5 mμsec for a ½% solution to 11 mμsec for a crystal. For stilbene and diphenylacetylene crystals, they measured t_f to be 3.1 and 2.5 mμsec, respectively. The effect of crystal size on t_f was investigated by Birks and Little[73] who used the phase-shift method and observed t_f for thick single crystals exceeded by many times that for microcrystalline specimens. The data for anthracene and terphenyl represent two extreme cases. Whereas in the former the t_f increases from 3.5±1.0 mμsec for microcrystalline specimens to 14±2.0 mμsec for 1-cm³ single crystals, in the latter it changes from 3.5±1.0 mμsec for powder to 3.8±1.0 sec for 2-mm thick single crystals. Accounting for the observed increase in decay times in crystals by self-absorption and re-emission of the primary molecular fluorescence, they calculate the decay time t_f of technical fluorescence at 12.6±3.5 mμsec which agrees, within experimental error, with the experimental value 14±2.0 mμsec. They calculated the decay time $(t_f)_{00}$ of primary molecular fluorescence to be 3.1+0.8 mμsec in agreement with the experimental value 3.5±1 mμsec. Bose *et al.*[74] have observed that under x-ray excitation the decay times of anthracene and naphthacene emissions in a green anthracene crystal isolated by suitable filters were practically identical.

Splendid as the success of the photon cascade theory seems to be in interpreting the energy transfer mechanism in pure aromatic crystals, it is not so in mixed crystals. In fact, in mixed crystals it is more qualitative than quantitative and must be considered with caution. The basic fact utilized by the theory, *viz.*, that the primary photons emitted in the region of the first ab-

sorption band system of a crystal are reabsorbed completely in this region due to very high absorption coefficients (10^2-10^3) is violated in the case of energy transfer from the host lattice to impurity molecules in mixed crystals. In spite of very high absorption coefficients of impurity molecules the effective absorption by a mixed crystal in the region of impurity absorption is much short of being total, unlike in pure crystals, because of the very low concentrations ($10^{-4}-10^{-5}$) mole solute/mole solvent at which the transfer of energy is almost total. The fluorescent spectrum studied by reflection, instead of transmission, to eliminate the small absorption effect of a thin microcrystalline layer of anthracene containing low percentage of naphthacene deposited from xylene solution on a fused quartz plate exhibits the naphthacene fluorescence bands in high intensity.[75] The result of drawing a parallelism between absorption effects due to the host lattice and impurity molecules is evident from the following considerations.

The relation

$$q_{ex}=\frac{1}{1+(K_y[Y]/K_{ex})}=\frac{1}{1+K[Y]},$$

where q_{ex} = technical fluorescence quantum efficiency of the host crystal X, K_y = probability of photon capture by the impurity y, K_{ex} = probability of photon escape in X crystal fluorescence, and $[Y]$ = concentration of Y, derived on the photon cascade theory in the absence of internal quenching, is similar to $N_x=1/(1+K[Y])$, where N_x = technical quantum efficiency of X-crystal luorescence, K = exciton capture probability of Y elative to that of X, derivable from the exciton theory. In both of them the important quantity is the energy transfer parameter k which determines the efficiency of the process. The value of k determined by Bowen *et al.* from the experimental N_x *vs* $[Y]$ curve for anthracene-contaminated naphthalene crystals excited by 2900 to 3000 A was 5×10^4 and the value obtained by Wright who used 2540 A as the exciting radiation was 4×10^4. In the relation $K_{ex}+K_x+K_y$, $[Y]=1$ where K_x = photon capture probability of X, given by the cascade theory, putting $Y=2.5\times10^{-5}$ mole, anthracene per molar naphthalene for equal intensities of the components and assuming the most favorable but experimentally unrealized condition $K_y=1$, we have $K_{ex}+K_x+2.5\times10^{-5}=1$. As the theory assumes no interaction between the host and the guest molecules, K should not differ from its value in a pure crystal. Substituting $K_x=0.9565$ from scintillation data which always gives a somewhat larger value, we have $k_{ex}=4.3475\times10^{-2}$ and $k=23$ far away from the experimental value. The only support for the theory in mixed crystals is Bowen and Mikiewicz's[76] result that the intensities of anthracene naphthacene fluorescence components become equal at 1.8×10^{-5} g naphthacene/g anthracene in anthracene-naphthacene crystals and at 9.10^{-5} g/g in solution, giving a ratio 0.2. The explanation that this difference results from the reduction of the effective absorption coefficient in solutions due to random alignment by a factor 0.25 relative to that in crystals where the Y molecules align parallel to X molecules applies to all such crystals and is not supported by the experimental facts that light in a double refracting crystal is bifurcated into two perpendicularly polarized components and that the absorption coefficients of a substance such as anthracene in solution are greater[77] than those in crystal by a factor ~8. Moreover, the disagreement by 25% is glaring.

5. SCINTILLATIONS FROM ORGANIC CRYSTALS

The scintillation property of fluorescent organic crystals has made them of great use in scintillation counting of nuclear radiations, but there seems to have been little attempt to understand its nature until the recent work of Taylor *et al.*,[8] Franzen *et al.*, Hopkins, Birks, etc.[78–82] We review the fundamental facts in the scintillation process because any satisfactory theory of the fluorescent process in these crystals must not ignore them. That the energy transfer mechanism in organic crystals under photon or corpuscular excitation is qualitatively independent of the mode of excitation seems to be borne out in Birk's[83] experiments. Using crystals of naphthacene containing different concentrations of anthracene he investigated their scintillation response to alpha particles. The intensities of naphthalene (N) and anthracene (A) emissions were measured separately by introducing suitable filters between the crystals and the photo tube. His plots of (N) and (A) fluorescence intensities, relative to pure crystal, against A concentrations, show that not only the N fluorescence is progressively suppressed with A concentration but also the quantity suppressed in N reappears in A (Fig. 10). The experimental curves were excellently reproduced in the theoretical curves obtained from the relation $n=1/(1+kx)$ derived by him from the exciton theory of energy transfer where n = relative intensity of radia-

tions, k = the exciton capture probability of an anthracene molecule relative to that of a naphthalene molecule, x = anthracene concentration in moles per mole of naphthalene; with $k=43$ for α particles. These curves are similar to those obtained by Bowen *et al.*[84] and Wright *et al.*[85] in case of photofluorescence of anthracene in naphthalene with $k=5\times10^4$.

A similar relation was derived by Birks and Black[86] on the exciton to account successfully for the irreparable deterioration in anthracene scintillation response produced by a prolonged intense α-particle bombardment so as to cause a permanent molecular damage as reported by Birks[87] and Wright.[88] They regard the damaged molecules as quenching centers just as quenching impurity molecules in a host lattice and found a value 1000 for k which is the exciton capture probability of a damaged molecule relative to an undamaged anthracene molecule.

The investigations of the scintillation response S of anthracene to protons of $E\leq17$ Mev by Franzen *et al.*,[78] Taylor *et al.*,[79] and Frey *et al.*[80] to electrons of E from 1 Kev to 3 Mev by Jentschke *et al.*[81] and Hopkins,[82] to α particle of $E\leq2.1$ Mev by Birks[87] and Taylor *et al.*,[79] to deuterons of $E\leq11$ Mev by Taylor *et al.*, show that the response S of anthracene to an ionizing particle of energy E and residual range r, depends on the nature of the particle and is proportional to E above a certain energy level. Measurements of the relative response of other organic crystals such as naphthalene,[87] stilbene,[79] terphenyl,[89] etc., and of organic solutions[90] to different particles show that they behave in the same manner as anthracene so that the behavior of anthracene can be regarded as typical of the organic substances studied. The $S-E$ curves of anthracene for different ionizing radiations are shown in Fig. 11(a). Birks' investigations[91] deserve special mention in that, unlike others, he compared the scintillation response S of anthracene and other crystals to different ionizing particles, by considering not the $S-E$ curve but the variation of the specific fluorescence ds/dr (expressed in arbitrary units of volts/cm air equivalent) with the specific energy loss dE/dr (measured in Mev/cm air equivalent) where r (measured in air equivalent) is the residual range of the particle within the crystal. He showed that the nonlinear portion of the $S-E$ curves was due to the nonlinear variation of the specific fluorescence with the specific energy loss. At low values of dE/dr (electrons of $E>125$ Kev) ds/dr increases linearly with correspondence to S being proportional to E. At high values of dE/dr (α particles of $E<5$ Mev) ds/dr is practically constant so that the scintillation S is proportional to the residual range r of the particle rather than to its energy E. This linearity in the $S-r$ curves for anthracene, terphenyl, and stilbene was found to hold good for r about 8 mm. The ds/dr *vs* dE/dr curve for anthracene and $S-r$ curve for stilbene are shown [Fig. 11(b) and Fig. 12].

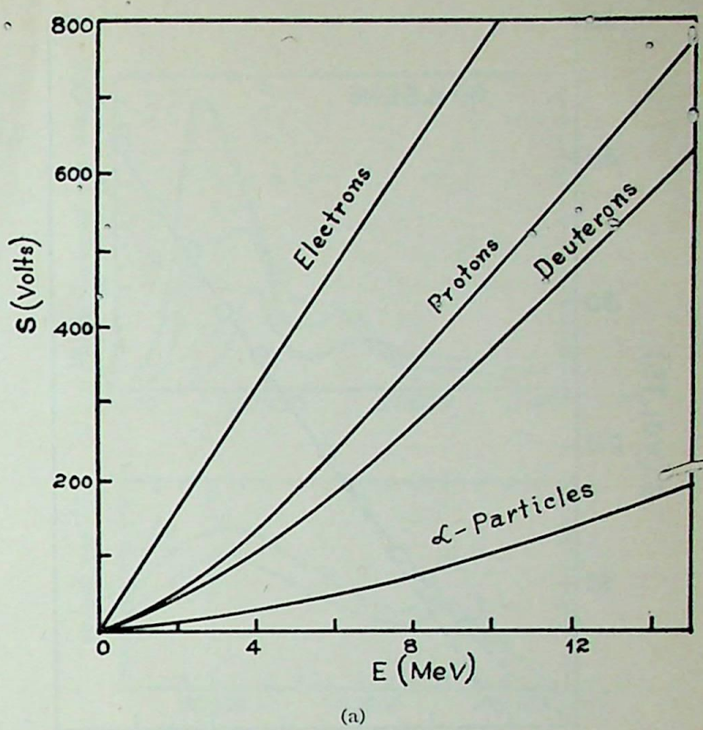

FIG. 11. (a) Relative scintillation intensity (S) of anthracene, produced by different ionizing particles, as a function of their energy (E) (after Jentschke *et al.*). (b) Specific fluorescence *vs* specific energy loss for anthracene (after Birks).

The exciton theory was extended by Birks[92] to account for the foregoing experimental facts. The passage of an ionizing particle through the crystal produces along its path a local concentration of damaged or ionized molecules and he regards them as quenching agents for the excitons produced by the ionizing particle. The linear density of excitons produced and the local concentration of nonradiative molecules at any point on the particle track are both proportional to the specific energy loss of the particle and can be put equal to $A(dE/dr)$ and $B(dE/dr)$ molecules per undamaged molecule, respectively. Denoting by k the exciton capture probability of a damaged molecule relative to

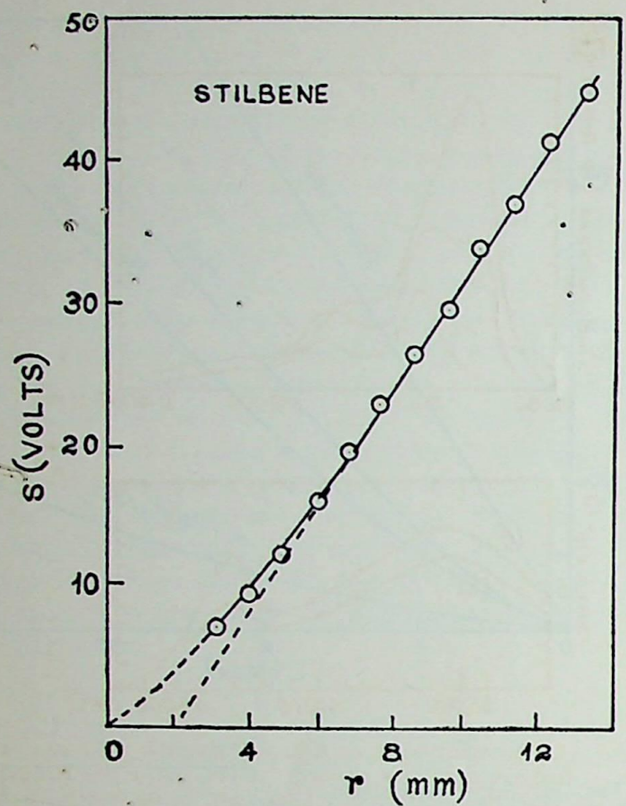

FIG. 12. Scintillation response of stilbene to α particles as a function of their air range r (after King and Birks).

an undamaged one, he deduces the relation,

$$\frac{ds}{dr}=\frac{A(dE/dr)}{1+KB(dE/dr)}, \tag{49}$$

which is reduced to $ds/dr=A(dE/dr)$ at low values of dE/dr and to $ds/dr=A/KB=$constant, at high values of dE/dr in agreement with observed facts. The experimental values of dE/dr and ds/dr used for substitution in Eq. (49) were obtained from the observations of Birks,[87] Curie,[93] Livingstone and Bethe,[94] and Bethe[95] and gave for $A=82.5$, $KB=7.15$ in anthracene.

The variation of dS/dr with dE/dr calculated from (49) agrees well with the experimental curve obtained for anthracene by Jentscke *et al.*[81] as shown in Fig. 11. The $S-E$ curve for electrons, protons, α particles, etc., calculated from (49) are in excellent agreement with those obtained experimentally.[96]

To account for the observed nonlinearity in the $S-r$ curves for $r<8$ mm, Birks[96] introduced a multiplying factor ϕ in (49) in consideration of the different behavior of excitons produced near the crystal surface. The function ϕ is given by

$$\phi=1-\tfrac{1}{2}\left\{\exp\left(-\frac{r}{a_0}\right)-\left(\frac{r}{a_0}\right)E_i\left(\frac{r}{a_0}\right)\right\},$$

where a_0—mean free path of an exciton and $E_i(r/a_0)$ exponential integral. The experimental $\phi-r$ curve for electrons in anthracene agrees well with the theoretical one.

The absolute efficiency of scintillation, i.e., the total energy of fluorescence emission/total energy of scintillation particles, of anthracene was measured by Birks and Szendrei[97] to be $3.76(\pm0.07)\%$ for thick anthracene crystals at room temperature, excited by fast electrons. This corresponds to an energy expenditure $E=70.5(\pm3.8)$ ev per fluorescence photon. The cascade theory formulated by Birks gave $E=68$ ev per photon in agreement with the experimental value.

Liebson[72] investigated the temperature dependence of the scintillation response S and the scintillation decay time t for anthracene from 103° to 283°K. His results show that a linear relationship between $\log_{10}S$ and t_1 holds good. Birks[98] worked out the relationship between S and t_1 on the photon cascade theory in $\log S=\log A+Bt_1$ where A is a constant and $B=\log q_0 t_0$, q_0 being the quantum efficiency of photon emission, occurring in cascade and of molecular decay time t_0. Substituting the experimental value of B from the graph and $q_0=0.9$, Birks found $t=3.8$ mμsec for the molecular decay time of anthracene at room temperature in excellent agreement with the experimental value 3.5 ± 1.0 mμsec obtained by Birks and Little.[73]

Sangster and Irvine[99] have studied the scintillation and photofluorescence behavior of a large number of crystalline organic compounds and the utility of Birks's photon cascade theory of the scintillation process has been demonstrated.

6. PHOTOCONDUCTIVITY OF ORGANIC CRYSTALS

Byke and Bork,[100] and Volmer[101] observed that anthracene crystals begin to photoconduct under the irradiation with wavelengths shorter than 4000 A. Later works of Putseiko, Akamato and Inokuchi, Vartanyan, Inokuchi, Eley *et al.*,[102] Mette and Pick,[103] Northrop and Simpson,[104] and Lyons and Morris[105] have confirmed that not only photoconduction but also semiconduction takes place in some aromatic crystals. This photoconductivity effect raises the question whether production and migration of holes have anything to do with the transport of excitation energy

through the anthracene lattice, even though want of any evidence of ionization in the anthracene lattice led Franck and Livingston[9] to discard the electron migration mechanism. Recent studies of the photoconductivity of anthracene have been made by Carswell,[106] Carswell and Lyons,[107] Chynoweth and Schneider,[108,109] and Bree, Carswell, and Lyons.[110] Carswell and Lyons' experimental arrangement uses a single anthracene crystal sublimed in a CO_2 atmosphere, mounted with Aquadag on platinum electrodes and irradiated with monochromatic radiation. Their important observations are: (a) plot of photocurrent *vs* frequency[106] of exciting radiations closely reproduces the optical absorption spectrum (Fig. 13), (b) the ratio of the current produced with light polarized parallel to the *b*-crystal axis to that parallel to the *a*-crystal axis was 1.5, using a mercury 3650 A light source[111]; (c) the photocurrent is proportional to the intensity of light; (d) quantum efficiency is approximately 10^{-4}, under his experimental conditions, constant over the near ultraviolet, and nearly equal to the fluorescence quantum efficiency; (e) the intentional incorporation of naphthacene as an impurity in the anthracene lattice so as to change the relative heights of the 5325 A and 4425 A fluorescent bands to 37:1 apparently affects neither the photocurrent nor the time constant.[111] The investigations of Chynoweth and Schneider[109] are of great significance in that their results support the adoption in organic crystals of the conventional energy band picture usually associated with inorganic crystals. The fact that irradiation of anthracene crystals within the fundamental absorption spectrum cannot liberate electrons completely,[112] combined with their observation that the majority of the carriers are positive holes suggests to them the following mechanism: light absorption raises the electrons either directly or through the intermediate process of exciton formation, into a metastable level from which they can either recombine with their holes, emitting fluorescence, or are trapped in a relatively stable level. Under the action of the field the holes drift through the lattice, but the drift velocity depends upon hole traps of different depths. Under steady-state conditions the rate of creation of carriers equals the rate of recombination between positive holes in the full band and the trapped electrons, as also the rate of trapping of carriers equals the rate of detrapping.

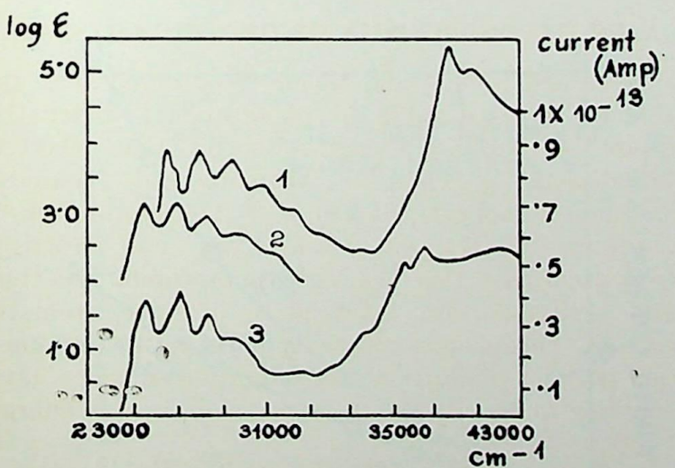

FIG. 13. (1) Solution absorption spectrum of anthracene. (2) Crystal absorption spectrum of anthracene. (3) Spectral photocurrent curve in anthracene crystal. Plot of photocurrent *vs* frequency of exciting radiations showing reproduction of the optical absorption spectrum (after Carswell).

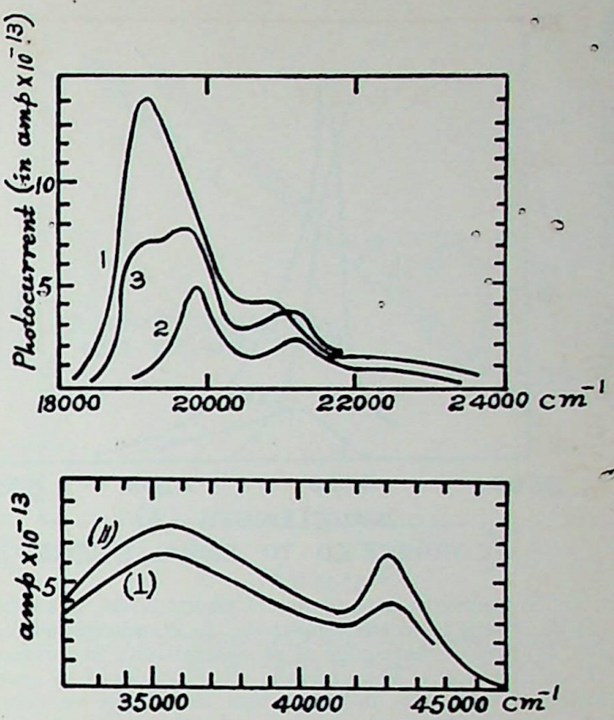

FIG. 14. Photocurrent in naphthacene single crystal as a function of frequency, in two ranges of wavelengths. In 1, light is polarized $||b$; in 2, $\perp b$; in 3, unpolarized. In the lower diagram "||, ⊥" are with respect to a direction which makes 12° with the *b* crystallographic axis (after Bree and Lyons).

If this mechanism is to be adopted for the emission of characteristic fluorescence of anthracene, it remains to be seen how it explains the want of reproduction of some photoconductivity phenomena in corresponding fluorescent phenomena as noted in (d) above. Leaving aside the question of transport of energy through the lattice of anthracene, the observation (e) made by Carswell suggests that immediate transfer of energy to naphthacene or pentacene in an impure anthracene crystal takes place by a mechanism other than hole migration.

The correspondence between the optical absorption spectrum and the photoconductance curve of an anthracene crystal, as observed above, led Bree and Lyons[54] to study the ultraviolet polarized spectrum of tetracene

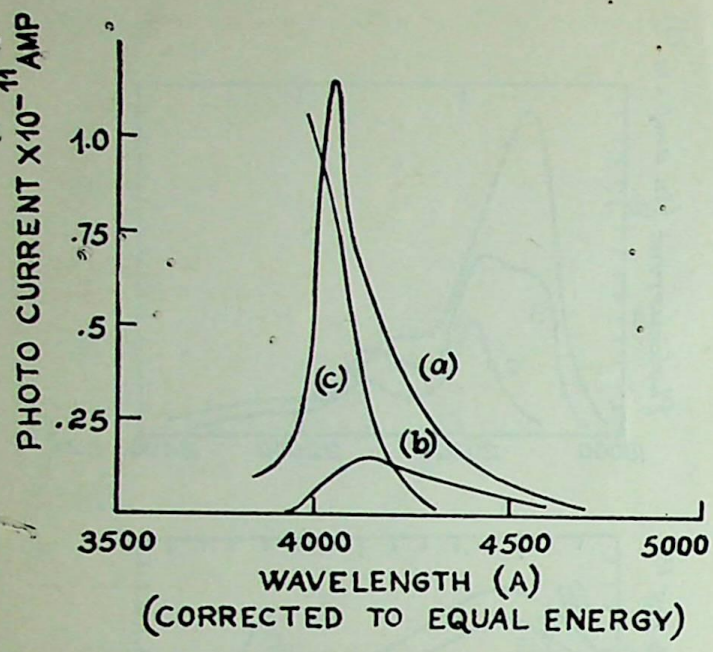

FIG. 15. Wavelength dependence of photocurrent in sandwich cell; (*a*) illuminated electrode positive, (*b*) illuminated electrode negative, (*c*) approximate edge of photosensitivity in surface cell (after Compton *et al.*). The observed effect produced by reversal of polarity of electrodes indicates that the charge carriers are mostly positive holes.

single crystals by the photoconductance method. They observed that the first system is definitely *b*-axis polarized and exhibits Davydov splitting (Fig. 14) as discussed in Sec. 3. Lyons and Morris[105] investigated the spectral dependence of photocurrent in naphthalene, phenanthrene, diphenyl, and *p*-terphenyl and compared it with the solution absorption spectra in the compounds. The photoconductivity takes place in the absorption region and not outside it. The measurements of Riehl,[113] Bree, Carswell, and Lyons[110] suggest that there is no true bulk photocurrent in anthracene and that the photoconductivity in anthracene is a surface phenomenon. This led Lyons[114] to explain the spectral dependence of photoconductivity in a surface cell on the assumption that the light energy absorbed by the crystal creates excitons, and that only those excitons that can migrate from their points of origin to the surface layer can generate charge carriers. The number n of excitons reaching the surface is given by

$$n=KI_0\left[\frac{E}{1-q}-\frac{E_q^2}{2}\left\{2(1-q)^2+\frac{1}{1-q}\right\}+E^3\right], \quad (50)$$

where E denotes the optical density of a molecular layer, I is the intensity of the incident light, q is the probability that an exciton crosses a layer of molecules, and k is a constant depending upon the specimen. If E is small, then neglecting higher powers of E, $n=KI_0E/(1-q)$ and the photocurrent is given by

$$i=e\mu V=K'I_0VE/(1-q), \quad (51)$$

where μ is the mobility of the charge carrier and V is the applied voltage. The photocurrent is linearly dependent on (a) the optical density of the crystal, (b) the incident light intensity, and (c) the applied voltage. The linear dependence on the incident light intensity and on the applied voltage was demonstrated by the investigations of Carswell and Lyons[107] and Chynoweth and Schneider,[108] respectively. Lyons[114] showed that, in the case of the tetracene crystal, the plot of optical density of the crystal against photocurrent was a straight line and thus exhibited the predicted dependence.

A recent detailed investigation of surface and bulk photoconductivity of anthracene was undertaken by Compton, Schneider, and Waddington.[115] They used three types of crystals, namely, large scintillation crystals, thin layer crystals grown from dimethyl-

formamide solutions, and sublimation flakes, and practically got rid of the space-charge effect, observed by earlier workers, by using electrodes of colloidal graphite, evaporated metals, and silver paste to secure better contacts with the crystal. To investigate the bulk photocurrent, they constructed a sandwich cell fitted with a guard ring on the surface separating the two electrodes. [One of the electrodes, called the front electrode, which was transparent, conducting and receiving the exciting light, was connected to a stabilized source of power; the other electrode, called the rear electrode, was connected to a microammeter.] If the guard ring is earthed, surface current is prevented from reaching the rear electrode.

Besides confirming the reported spectral dependence of surface photoconductivity and that the photocurrent is mostly caused by the mobility of positive holes, they arrived at the following results:

(1) Anthracene crystals exhibit a true bulk photoconductivity which is not affected by the nature of ambient gases. The bulk photocurrent in an anthracene sandwich cell is much less than the photocurrent in a surface cell under comparable conditions. The spectral dependence of bulk photocurrent is unlike that of surface photocurrent in that the maximum photocurrent occurs on the long wavelength side of the anthracene absorption band (Fig. 15).

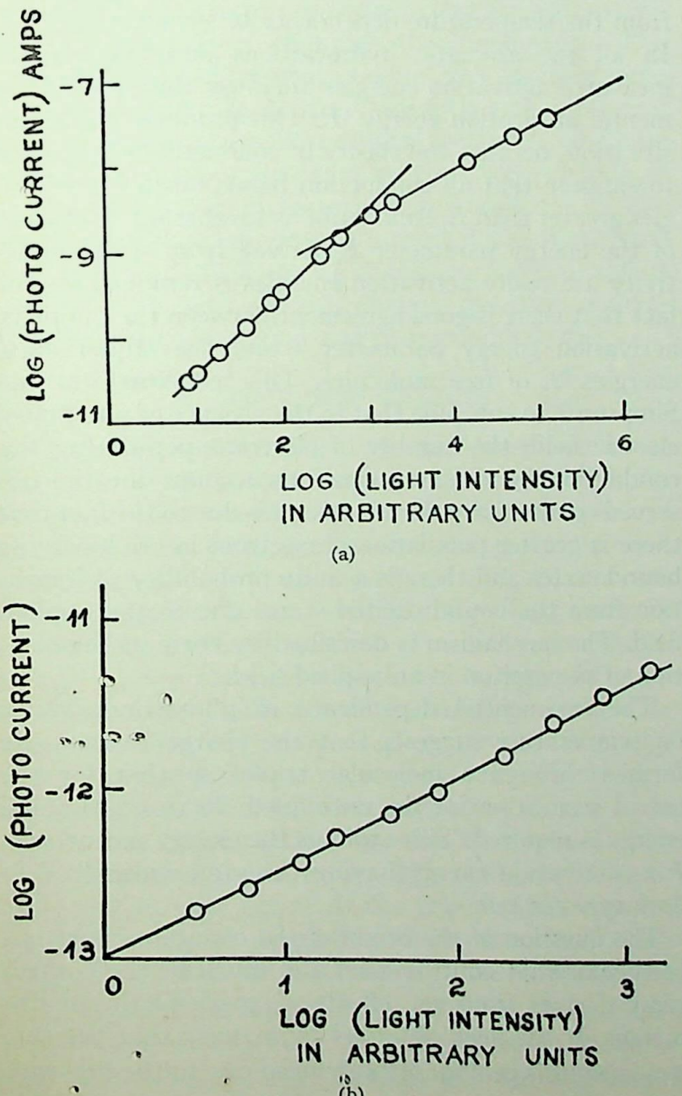

FIG. 17. Photocurrent as a function of light intensity (a) surface cell and (b) sandwich cell (after Compton *et al.*).

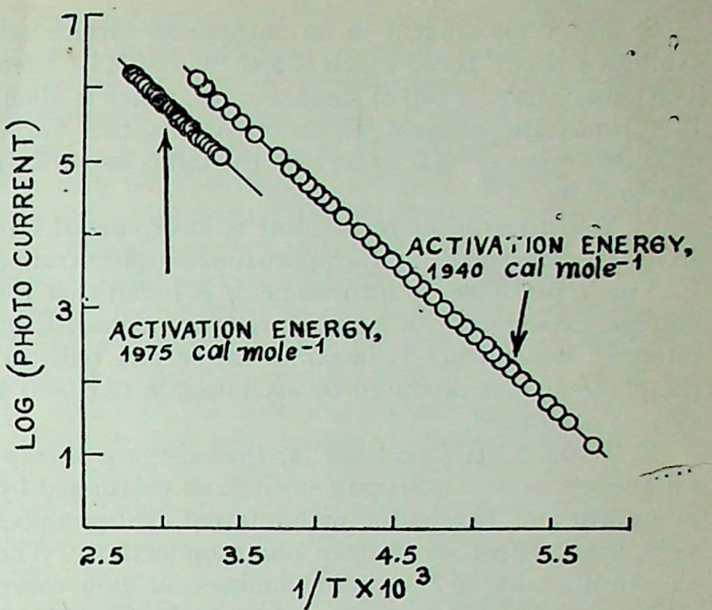

FIG. 18. Photocurrent as a function of temperature (after Compton *et al.*).

(2) The surface and bulk photocurrent in anthracene, generally nonohmic, exhibits an ohmic dependence on applied voltage at very low strength (less than 60 v cm^{-1} in a surface cell) and increases at a rate higher than linear at higher field strengths. The photocurrent, i, showed no sign of saturation, even with 25 kv cm^{-1} in a surface and 20 kv cm^{-1} in a sandwich cell (Fig. 16). Plots of V/i against V, in the case of a surface cell were straight lines, indicating that i is proportional not to V, as demanded by Lyons' theory, but to $V/(a-bV)$.

(3) In the surface cell the photocurrent shows a linear dependence on the light intensity except at very high level of intensity, whereas in a sandwich cell it varies as the square root of the light intensity (Fig. 17).

(4) The photocurrent displays an interesting dependence on crystal orientation; it is greatest in the b direction, about ten times smaller in the a direction, and one-hundred times so in the c direction. This indicates that the charge carriers are more mobile in the b direction than in the a and c directions by factors 10 and 100, respectively.

(5) The photocurrent studied in a surface cell or in a sandwich cell over a temperature range from 55 or 70°C to −130°C in an atmosphere of pure dry argon, follows the relation

$$i = i_0 e^{(-E/KT)},$$

where $E = 0.172 \pm 003$ ev in a surface cell and 0.176 ± 010 ev for a sandwich cell (Fig. 18).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

(6) The photocurrent in an anthracene surface cell exhibits a decay time, which is less than 30×10^{-5} sec. The decay shows a tail of some seconds, which is about 10^{-3} times the original photocurrent. As this varies markedly from crystal to crystal, the tail is most likely due to flaws.

(7) When tetracene or acridine is incorporated into an anthracene crystal in the approximate concentration 10^{-3} mole per mole of anthracene, it is found that the voltage dependence of photocurrent is unaltered, its intensity dependence is linear in the surface cell, and the photocurrent produced by excitation in the 3800 A system is reduced.

(8) There is little evidence for the existence of trapping levels in an anthracene crystal, as postulated by many workers. Irradiation with infrared light produces very small effect on surface photoconductivity. The electrical analog of the thermoluminescent glow curve shows that the concentration of traps of depth from 0.15 to 0.5 ev is less than 10^8 cm^{-3} in a pure anthracene surface or sandwich cell, and this is not dependent on the nature of the ambient gas. These experimental results are explained on the following model: The carriers of charge, which are positive holes, are generated in the bulk as well as on the surface, the carrier mobility being greater in the latter case than in the former. Lyons' calculations can be applied with the modification that q denotes the probability of charge carrier crossing a molecular layer. The photocurrent thus remains proportional to the optical density as observed by Lyons but the smaller the optical density is, the greater is the proportion of carriers formed at a good depth below the surface. This gives rise to the long wavelength tail of surface current in thick crystals and becomes of great importance in a sandwich cell. The photocurrent in the bulk is recombination limited, i.e., the charge carriers (positive holes) end their life by recombination before reaching the electrodes.

In the surface cell these carriers migrate to the surface along the shortest route, but because the surface in a real crystal is not perfectly flat, this route at many points will not be perpendicular to the field direction. Thus, the probability q of a charge carrier crossing a molecular layer is affected by V and if the phenomenon is averaged over the distance between electrodes, q can be expressed as $q=a+bV$. The equation for i becomes

$$i=\frac{KVI_0E}{1-a-bV}=\frac{KVI_0E}{a'-bV},$$

which explains the experimental fact that V/i depends linearly on V. The mechanism of formation of charge carriers in anthracene and other organic crystals is not clearly understood. Though photoconductivity is produced by absorption of light, it is not a primary product of light absorption because the first excited states of anthracene crystal are exciton states where the electrons and holes, created by the act of light absorption, migrate remaining bound to each other and produce no photocurrent. The experimental facts that the quantum efficiency for photoconductivity is of the order of 10^{-4}, and that the photocurrent is profoundly influenced by impurities (as observed by Carswell and Lyons[107] and Compton *et al.*[115]), and reduced by neutron irradiation (as observed by the latter group), cannot be explained on such an assumption.

In many photoconductors in which infrared irradiation has little effect on the photocurrent, optical and thermal formation of charge carriers requires identical energies and the absorption edge occurs corresponding to the energy E in the equation for semiconductivity $\sigma=\sigma_0e^{-E/2kT}$. This relation is obeyed by the aromatic[113] hydrocarbons such as anthracene, naphthacene, pentacene, etc. If the generation of charge carriers is not a primary product of light absorption in anthracene, one cannot expect that the energy parameter E would have the energy value corresponding to the absorption edge. In fact, the energy 3.2 ev associated with an exciton in the 3800 system is greater than the activation energy of semiconductance 1.63 ev as found by many workers[103,104] from the temperature dependence of semiconductivity. In all the aromatic hydrocarbons investigated, the measured activation energies are lower than the fundamental absorption energy ^1E. This produces a difficult situation, because the theory of conductivity leads one to suppose that all conduction bands must have energies greater than E. Any doubt as to whether the values of the energy parameter E derived from semiconductivity are really activation energies is removed by the fact that there is good agreement between the impurity activation energy parameter ϵ and the triplet state energies ^3E of free molecules. This led Northrop and Simpson[104] to conclude that in the absence of an applied electric field, the number of electrons populating the conduction band is too small to account for the observed conductivity. Conductivity is due to the fact that there is greater population of electrons in the low lying bound states and there is a finite probability of ionization from the bound excited states due to the applied field. The mechanism is described by them as dissociation of the exciton in an applied field.

The exponential dependence of photoconductivity on temperature suggests that the charge carriers are formed through a molecular triplet so that for the actual separation for the uncoupled electrons, thermal energy is required. This explains the energy parameters E as activation energy having the same value 0.17 in both types of cell.

The question of the origin of the charge carriers has been somewhat controversial and much of the controversy derives from the effects of gases on the photocurrent. It has been observed by many[116] that the surface current is profoundly enhanced due to the presence of adsorbed gases such as O_2, SO_2, etc. This led Bree

[116] H. J. Zinzer, Z. Naturforsch. 11a, 306 (1956).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and Lyons to suggest that oxygen serves as a catalyst in the formation of a triplet level which reacts to form the biradical intermediate AOO. When the AOO dissociates into ions, charges are liberated and the positive holes move through the lattice. This scheme of formation of charge carriers is, however, not properly equipped to explain the origin of bulk photocurrent established by Compton *et al.* who regard fluorescence and photoconductivity as processes competing with each other when an exciton ends its life. This is supported by experimental investigations of Zinzer[116] who found that prolonged α-ray bombardment reduces the fluorescence and the surface photocurrent and by those of Compton *et al.* who observe that neutron bombardment reduces both bulk and surface photocurrent as well as fluorescence. Compton *et al.* observe that the incorporation of tetracene into anthracene lattice also reduces the photocurrent in the 3800 system of anthracene, though Carswell and Lyons find that introduction of 10^{-4} M tetracene into anthracene increases the photocurrent, especially in the region of the second electronic transition (40 000 cm). Many workers[21,2] observed that incorporation of tetracene or acridine into the anthracene lattice suppresses or quenches the fluorescence. The quantum efficiency of photoconductivity of anthracene is 1. The former figure may mean that the range of charge carriers is small compared with the electrode separation which is suported by the observed lack of saturation in the photocurrent. A knowledge of the carrier mobility is required to convert detected currents into quantum efficiency of charge formation, and it remains to be seen whether there is quantum equivalence between absorption and photoconductivity.

7. SOME NEW RESULTS

The contents of the Secs. 3, 4, and 5 seem to indicate that, in most of the aromatic crystals investigated, the energy of excitation can migrate away from the place of excitation in the form of excitons, and that if the exciton is annihilated deep in such a crystal with the emission of fluorescence radiation, the emitted radiation may be absorbed in a photon cascade process by the crystal having intense absorption band in the region of emission. But the sections do not furnish any detailed information regarding the place of terminus of the energy transport, and it is not known how the final stage of the transfer is executed in a pure crystal, nor in an impure one. Polarization properties of crystal absorption and emission are expected to yield valuable information in this regard. If the crystal fluorescence is due to the reverse of photon absorption, fluorescence should give the same polarization ratio as absorption, provided both correspond to the same electronic transition. Experimental observations show that the polarization ratio of absorption (3800 A) and the fluorescence (corresponding to the same electronic transition) spectra are very different.

The polarization ratio for absorption of light in the c' direction of an anthracene crystal, when c' is perpendicular to the a and b crystallographic axes, has been measured by Craig and Hobbins[43] to be 1.8:1 and by Ganguly, Chaudhury, and Mukherjee[49] to be 1.5:1. The ratio of fluorescence intensity along the same directions, observed in the c' direction, has been determined by Ferguson and Schneider[117] to have the value 5:1 and the value obtained by Chaudhury[118] who corrected for all probable errors, is 4.3:1. Ganguly and Chaudhury[119] calculated on the basis of an oriented gas model that the polarization ratio (I_b/I_a) is given by the square of the cotangent of the angle which the active molecular axis (projected on the ab face) makes with b axis of the crystal. Craig and Hobbins[43] showed that the first-order perturbation methods applied to the exciton theory gives the same result. For an anthracene crystal it is 7.8:1 which is reduced to 6.5:1 on making allowance for torsional oscillations. Ferguson and Schneider argue that if the value 1.8:1 for absorption is accounted for, as was done by Craig,[120] by assuming a crystal induced mixing of the first two excited states of an anthracene molecule, the value of 4–5:1 for fluorescence, being nearer the exciton theory prediction, implies that the fluorescence is emitted from a molecule situated at a lattice dislocation where the symmetry elements of the lattice are not maintained. The different values for absorption and fluorescence I_b/I_a may be due to the fact that fluorescence is emitted from a molecule situated at a place where the principal directions of transition are rotated with regard to those of crystal absorption. Thus, these facts seem to establish the idea that an exciton in an anthracene crystal ends its life by being captured by a molecule situated at a dislocation from where the fluorescence is emitted.

When naphthacene molecules are present in an anthracene crystal that is excited by ultraviolet radiation, the naphthacene molecules may fluoresce by any one of the processes described in Sec. 1. If the photon cascade process is responsible, the decay time for fluorescence of anthracene would be different from the decay time of fluorescence of naphthacene in a crystal containing naphthacene as impurity. Unfortunately, there are hardly any useful data on decay times of fluorescence in mixed crystals, except those of Bose[74] which are not free from ambiguity. In this laboratory we have measured the optical densities of an anthracene crystal containing naphthacene molecules and calculated the effect of naphthacene absorption on anthracene fluorescence, according to the formula[118]

$$\frac{f_r}{f_0}=\frac{\mu_1 l}{\mu_1 l+\mu_2 l}\left\{\frac{1-e^{-(\mu_1+\mu_2)l}}{1-e^{-\mu_1 l}}\right\},$$

where f_r is the backward fluorescence intensity of anthracene if there is absorption, f_0 is the same for no absorption; $\mu_1 t$ is the optical density of this crystal at the exciting wavelength λ_1, $\mu_2 t$ that at the emitted wavelength λ_2. In our measurements, $t=9.9\times10^{-3}$ cm, $\mu_1 t\sim10^3$ at $\lambda_1=3650$ A; $\mu_2 t\sim1$ at $\lambda_2=4898$ A where the absorption intensity of naphthacene molecules is the greatest in the fluorescence region of anthracene and $f_r/f_0\simeq1$. Thus absorption cannot be held responsible for transfer of energy from anthracene to naphthacene.

It has also been observed in this laboratory that when naphthacene molecules are incorporated within the anthracene lattice, not only the absorption and fluorescence spectra of naphthacene molecules show polarization, but also the polarization ratio of absorption spectra of these molecules remains unaltered from that of pure anthracene crystal. This means that the naphthacene molecules are embedded in an anthracene lattice as substitutes for anthracene molecules, and also that they are coupled to the anthracene lattice in the same way as anthracene molecules themselves. Thus it may be inferred that if the fluorescence of anthracene occurs at molecules situated in imperfect regions of crystal lattice, so it is for naphthacene fluorescence. The transfer of excitation energy from anthracene to naphthacene molecules is half complete at a concentration of $c=1.8\times10^{-5}$ mole naphthacene per mole anthracene.[28] If the naphthacene molecules occur at lattice dislocations at the same concentration as anthracene molecules, which is quite reasonable in view of the foregoing facts, the probability that a naphthacene molecule receives the excitation energy, and emits it in the form of fluorescence, should be at least 5×10^4 times as great as that of an anthracene molecule.

When the intensity ratio of the polarized fluorescence band at 4450 A of an anthracene crystal along the *b* axis to that along the *a* axis is plotted against different concentrations of naphthacene in the crystal, it is observed that the ratio at first gradually increases, attains a maximum value, then decreases with increase of concentration of naphthacene. This increase of intensity ratio with increase of concentration of naphthacene at low concentration region excludes absorption process. But the fall of the intensity ratio of fluorescence of anthracene at high concentration region of naphthacene is difficult to explain if the absorption process is prohibited altogether.

8. SUMMARY

Though our knowledge of energy transfer in aromatic crystals has increased considerably, it has not reached the state of maturity required for a definite formulation of a general rule. Many aspects of the problem remain almost untouched. Except for Bowen *et al.* and Birks *et al.*, very few workers have measured the effect of crystal size and shape on the fluorescence intensity, nor the efficiency of transfer of energy in these crystals. Because a quantum mechanical resonance transfer process is independent of crystal size and shape, the importance of such measurements in distinguishing the photon cascade from resonance transfer cannot be overemphasized. More and more careful measurements would be worthwhile. There exist few data on the efficiency of energy transfer from a host molecule to an impurity as a function of the exciting wavelength. It is also not known whether naphthacene fluoresces with the same efficiency by transferred excitation energy as by direct absorption, though in a recent paper Simpson[60] has shown that the intensity of naphthacene fluorescence excited by absorption of fluorescence of anthracene is smaller than that under exciton excitation. Because of complete quenching of the fluorescence of anthracene, it cannot be concluded whether the fluorescence efficiency is or is not the same in both the cases. Careful study of the results show that the agreements between the predictions of the exciton theory of the molecular organic crystal and the observed spectroscopic data are only over all and not in details. Again, cascade theory cannot explain many experimental results, though it gives satisfactory solutions to the problem of mechanism of energy transfer in pure crystal. This shows that either data of greater precision or some modification in the theories must be introduced. Measurements of absorption coefficients have not been made in many of these crystals, pure or impure, with the result that values of the absorption coefficients in solutions are quoted in support of a theory in solids. The importance of temperature in emission and absorption cannot be denied, but it has been almost completely ignored. More data are required on photoconductivity. Results obtained by different workers on the same crystals not only differ but are sometimes contradictory: how the mobility is influenced by various factors needs to be known for clearer understanding of the subject. It is expected that the study of temperature effect on the efficiency of fluorescence, coefficients of absorption, energy transfer, and polarization will reveal facts of far-reaching consequences. We have undertaken some of the studies in this laboratory.

Note added in proof.—After the review had been sent for publication, some new works having some bearing on the subject matter of the review appeared. They are briefly described below.

Electronic states of aromatic crystals (Sec. 3).—The near ultraviolet polarized absorption spectra of some aromatic crystals of pyrene have been investigated by Ferguson[121] at room temperature and at 77°K, of 1,3,5-trichlorobenzene by Schnepp[122] at 42°K, of hexachlorobenzene by Schnepp and Kopelman[123] at liquid nitrogen and liquid helium temperature, and of durene by Schnepp and McClure[124] at 20°K. Whereas in the case of pyrene, Davydov splitting could be detected as a separation of 18 cm^{-1} between the *a*- and *b*-polarized components, the *a* component being of higher energy in 1,3,5-trichlorobenzene, hexachlorobenzene, and durene

[121] J. Ferguson, J. Chem. Phys. **28**, 765 (1958).
[122] O. Schnepp, J. Chem. Phys. **30**, 863 (1959).
[123] O. Schnepp and R. Kopelman, J. Chem. Phys. **30**, 368 (1959).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

crystals, no such splitting could be detected. If present, the splitting must not be greater than 5 cm^{-1} in the trichlorobenzene and hexachlorobenzene and 3 cm^{-1} in the durene crystal. In the case of the hexachlorobenzene crystal, the energy of separation between the two $K=0$ levels in the exciton band has been calculated to be 0.7 cm^{-1}.

Thus it appears that at least one of the low-lying excited electronic states of the pyrene crystal has the nature of exciton states, though in the case of the 1,3,5-trichlorobenzene, hexachlorobenzene, and durene crystals any such conclusion would be too hasty in view of the paucity of experimental data.

Photoconductivity of organic crystals (Sec. 6).—In a recent paper[125] Northrop and Simpson have published values of photocurrents of pure hydrocarbon crystals. They observed that the impurity molecules embedded in pure crystals which quench the fluorescence of pure substance reduce the photocurrent in the same ratio. Their other observations regarding dependence of photocurrent with light intensity, applied voltage, etc., are in agreement with previous publications. From these observations they propose that the interaction of two excitons is required to produce a single ionized molecule. Thus the production of charge carriers is explained. Compton *et al.*[126] studied photocurrent of anthracene crystals before and after neutron bombardment and concluded that conductivity was greatly reduced on bombardment. They further observed that dependence of photocurrent on wavelength and intensity of incident light remained unaltered after bombardment. Before bombardment the photocurrent was markedly nonohmic, after bombardment it was ohmic up to a field of 25 000 volts cm^{-1}. Before neutron bombardment the sample shows change of photocurrent when polarity of electrode is reversed, but this asymmetry disappears after irradiation. Kommandeur and Schneider[127] studied the photoconductivity in greater detail with very pure specimens of anthracene crystals and obtained results very different from previous ones. They observed that the maximum value of photocurrent corresponds to the minima of the absorption spectra. They also observed that the intensity dependence of photocurrent changes with wavelength, field direction, and even with magnitude of the applied field. These authors finally concluded that spectral response, voltage, and intensity dependence of photocurrent depend on the source and treatment of the crystals used, i.e., it depends on the density of imperfections of the crystals.

REVIEWS OF MODERN PHYSICS VOLUME 31, NUMBER 4 OCTOBER, 1959

Irreversible Thermodynamics of Nonlinear Processes and Noise in Driven Systems*

WILLIAM BERNARD† ‡ AND HERBERT B. CALLEN

University of Pennsylvania, Philadelphia 4, Pennsylvania

1. INTRODUCTION

THIS paper reviews and extends the theory of irreversible thermodynamics. The irreversible behavior of a system driven by externally applied forces has been studied extensively, but attention has been focused primarily on the first-order term in the driven response. Here we also consider the higher-order terms in the driven response and the random fluctuations, or noise, occurring during an irreversible process. In addition to the well-known relations between the linear response and the equilibrium fluctuations, several new relations are proved involving the nonlinear response, the driven noise, and the equilibrium fluctuations.

The method of analysis is statistical mechanical and general, neither assuming a specific model nor postulating Markoffian behavior. The purposes of the analysis are thermodynamic; that is, to investigate interrelationships among macroscopically observable characteristics of systems undergoing irreversible processes. In this sense the aim should be clearly differentiated from those other approaches which might be characterized as kinetic or statistical mechanical rather than thermodynamic.

The most direct approach to the problem of irreversibility is the kinetic approach, in which a specific model is immediately introduced. The essential features of the model may be expressed in terms of molecular collision probabilities, giving rise to the Boltzmann equation, or to some similarly detailed kinetic equation. This is the standard method of "transport theory," and it is the method characteristic of the theory of the solid state.

A considerably more general approach is one which we term the irreversible statistical mechanical approach. The purpose there is to develop a general formalism, analogous to the partition sum algorithm of equilibrium statistical mechanics, which would provide a systematic recipe for the calculation of any macroscopically ob-

servable characteristic of a system undergoing an irreversible process. No specific model is invoked; the aim is rather to provide a general formalism into which any particular model could be substituted to obtain explicit results. The irreversible statistical mechanical approach has not been completely successful as yet, but one type of partial result has been exploited widely. In this type of result the driven response of a system is obtained as a perturbation expansion in the applied forces. The various order response terms are typically expectation values of (multiple) commutators, taken with respect to the equilibrium system. It is, of course, hoped that a general algorithm for the computation of equilibrium commutator forms then will be developed to complete the general formalism.

The third approach is the thermodynamic approach which we adopt here. Although the statistical mechanical formalism is used to describe the motion, our purpose is not to compute either the response functions or the value of any quantities characterizing the equilibrium system. Our purpose is rather to explore the general interrelationships among different types of response functions and the equilibrium fluctuations, insisting, however, that the quantities so related each be macroscopically observable. Thus, for example, the equilibrium commutator forms in terms of which statistical mechanics expresses various response functions are not true observables of the equilibrium system. In order to give thermodynamic significance to statistical mechanical results, it is therefore necessary to re-express such quantities in terms of macroscopically observable symmetrized equilibrium forms, or anticommutators.

Three general classes of irreversible thermodynamic results have previously been obtained for first-order processes: (a) relationships between off-diagonal elements of the admittance—these are the Onsager reciprocity,[1,2] and its extension to non-Markoffian systems[3]; (b) the relationship between the first-order response and the second correlation moments of the equilibrium fluctuations—this is the so-called fluctuation-dissipation theorem[4,5]; (c) the relationship between the path distribution function for a driven system and the equilibrium fluctuations.[6–8]

The extensions of the theory which are developed here, and the general structure of irreversible thermodynamics, are summarized in the diagram in Fig. 1. The quantities appearing at the vertices of the diagrams denote the macroscopic observables, while the connecting lines indicate the existence of thermodynamic relationships. The arrowheads refer to the direction in

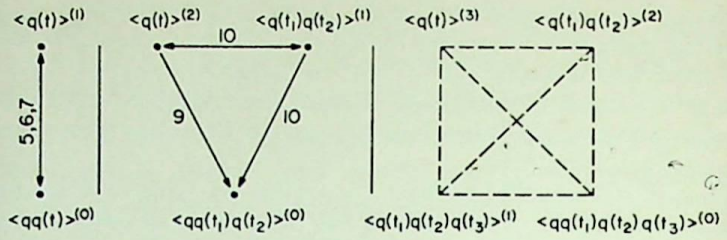

FIG. 1.

which specific relationships are developed in this paper, the numbers along the lines indicating the sections in which the various proofs appear.

The nature of the observables of interest can be made clear by the following considerations. Let $\langle q(t)\rangle$ denote the expectation value of the variable q at time t in a system driven by externally applied forces; that is, the driven response of the variable q. Further, let $\langle q(t)\rangle$ be expanded in powers of the applied forces. Then we label the first-order term in the response $\langle q(t)\rangle^{(1)}$, the second-order term $\langle q(t)\rangle^{(2)}$, etc. The zeroth-order term $\langle q(t)\rangle^{(0)} = \langle q\rangle^{(0)}$ is simply the average value of q in the equilibrium system. We similarly obtain a more detailed description of the driven system by introducing the expectation value $\langle q(t_1)q(t_2)\rangle$ of the product of the variable q at time t_1 with its value at time t_2; this is the second correlation moment of the random fluctuations, or noise, in the driven system. Again it is possible to expand $\langle q(t_1)q(t_2)\rangle$ in powers of the applied forces. We label the first-order term in the driven noise $\langle q(t_1)q(t_2)\rangle^{(1)}$, the second-order term $\langle q(t_1)q(t_2)\rangle^{(2)}$, and so on. The zeroth-order term $\langle q(t_1)q(t_2)\rangle^{(0)} = \langle qq(t_2-t_1)\rangle^{(0)}$ characterizes the spontaneous fluctuations in the equilibrium system. Similarly, it is possible to consider third- and high-order driven correlation moments.

There exists a definite hierarchy of irreversible thermodynamic relationships. The left-hand diagram represents the fluctuation-dissipation theorem, between the first-order response $\langle q(t)\rangle^{(1)}$ and the equilibrium second moment $\langle qq(t)\rangle^{(0)}$. The middle diagram indicates the triplet of relationships which exists among the second-order response $\langle q(t)\rangle^{(2)}$, the first-order term $\langle q(t_1)q(t_2)\rangle^{(1)}$ in the driven second moment (noise), and the third moment $\langle qq(t_1)q(t_2)\rangle^{(0)}$ of the spontaneous equilibrium fluctuations. The right-hand diagram indicates the cycle of interrelationships which may be presumed to exist among the next appropriate group of observables, although we do not consider this case explicitly.

In Secs. 2 to 4 the general statistical mechanical description of the time-evolution of a driven system is briefly reviewed. Sections 5 to 8 are devoted to a review of the existing first-order theory of irreversible thermodynamics. In Secs. 9 to 14 the general theory of irreversible thermodynamics is extended to the second-order response and the driven noise. Sections 13 and 14 are devoted to the irreversible thermodynamics of step-driven processes. In Secs. 15 and 16 the question of path distribution functions is considered, which may be regarded as the fundamental quantities of irreversible

thermodynamics in the sense that all macroscopic quantities are derivable therefrom.

3. THE TIME EVOLUTION OF DRIVEN OPERATORS

We consider a system, of which the unperturbed Hamiltonian is $H^{(0)}$, in interaction with a number of external driving systems or signal generators. The Hamiltonian of the composite system may typically be represented by

$$H=H^{(0)}+\sum_i F_iQ_i+H_{sg}, \tag{1}$$

where $Q_i=Q_i(q,p)$ is a function of the coordinates q and momenta p of the system of interest, $F_i=F_i(q',p')$ is a function of the coordinates q' and momenta p' of the ith signal generator, and H_{sg} denotes the Hamiltonians of the signal generators.

Whereas the dissipative system possesses a large number of degrees of freedom and a quasi-continuous spectrum of energy eigenvalues, the signal generators have relatively few degrees of freedom and an extremely high degree of excitation. Thus, the coordinates of the signal generators, and consequently the $F_i(q',p')$, are essentially classical functions of the time. Ignoring the term H_{sg} as being irrelevant to the system of interest, the perturbed Hamiltonian assumes the form

$$H=H^{(0)}+\sum_i F_i(t)Q_i. \tag{2}$$

We adopt the interpretation that the Hermitian operators $Q_i(q,p)$ correspond to thermodynamic extensive parameters of the system of interest, while the $F_i(t)$ represent the conjugate intensive parameters imposed upon the system by the various signal generators. Thus, $Q_i(q,p)$ might be the operator corresponding to the position of a movable piston (volume), the total number of particles, or the magnetic moment of the system. The respective imposed intensive parameter would then be the pressure, the electrochemical potential, or the applied magnetic field.

If the system is in equilibrium, with the temperature T, before the forces are applied, the expectation value of an operator Q_i at time t is

$$\langle Q_i(t)\rangle=\text{Trace}\,\rho^{(0)}Q_i(t), \tag{3}$$

where $\rho^{(0)}$ is the initial (unperturbed) canonical density operator

$$\rho^{(0)}=\exp[-\beta H^{(0)}]/\text{Tr}\exp[-\beta H^{(0)}],\quad \beta=1/kT, \tag{4}$$

and where the Heisenberg operator $Q_i(t)$ is defined by

$$Q_i(t)=U^\dagger(t)Q_iU(t). \tag{5}$$

The unitary time-evolution operator $U(t)$ satisfies the Schrödinger equation

$$\dot{U}(t)=\frac{1}{i\hbar}H(t)U(t)=\frac{i}{i\hbar}[H^{(0)}+\sum_i F_i(t)Q_i]U(t). \tag{6}$$

The differential equation (6) is equivalent to the integral equation

$$U(t)=\exp\left[-i\frac{H^{(0)}t}{\hbar}\right]\left[1+\frac{1}{i\hbar}\sum_i\int_{-\infty}^{t}dt_1F_i(t_1)Q_i^{(0)}(t_1)\times\exp\left[i\frac{H^{(0)}t_1}{\hbar}\right]U(t_1)\right] \tag{7}$$

the correctness of which can be verified by differentiation. $Q_i^{(0)}(t)$ represents the unperturbed Heisenberg operator

$$Q_i^{(0)}(t)=\exp\left[i\frac{H^{(0)}t}{\hbar}\right]Q_i\exp\left[-i\frac{H^{(0)}t}{\hbar}\right]. \tag{8}$$

The iterative solution of Eq. (7) is

$$U(t)=\exp\left[-i\frac{H^{(0)}t}{\hbar}\right]\sum_{n=0}^{\infty}\left(-\frac{1}{i\hbar}\right)^n\sum_{ij\cdots k}\int_{-\infty}^{t}dt_1\times\int_{-\infty}^{t_1}dt_2\cdots\int_{-\infty}^{t_{n-1}}dt_nF_i(t_1)F_j(t_2)\cdots\times F_k(t_n)Q_i^{(0)}(t_1)Q_j^{(0)}(t_2)\cdots Q_k^{(0)}(t_n). \tag{9}$$

The perturbation expansion of $Q_i(t)$ follows from Eqs. (5) and (9). The zeroth-order term is simply the unperturbed operator $Q_i^{(0)}(t)$. The first-order term $Q_i^{(1)}(t)$ is

$$Q_i^{(1)}(t)=-\frac{1}{i\hbar}\sum_i\int_{-\infty}^{t}dt_1F_j(t_1)[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-. \tag{10}$$

The second-order term $Q_i^{(2)}(t)$ is

$$Q_i^{(2)}(t)=\left(-\frac{1}{i\hbar}\right)^2\sum_{jk}\left\{-\int_{-\infty}^{t}dt_1F_j(t_1)\times\int_{-\infty}^{t}dt_2F_k(t_2)Q_j^{(0)}(t_1)Q_i^{(0)}(t)Q_k^{(0)}(t_2)+\int_{-\infty}^{t}dt_1F_j(t_1)\int_{-\infty}^{t_1}dt_2F_k(t_2)\times[Q_k^{(0)}(t_2)Q_j^{(0)}(t_1)Q_i^{(0)}(t)+Q_i^{(0)}(t)Q_j^{(0)}(t_1)Q_k^{(0)}(t_2)]\right\}. \tag{11}$$

In order to put the second-order term into a more suitable form, we decompose the t_2 integral of the first

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

term, so that

$$\int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t} dt_2 F_k(t_2) Q_j^{(0)}(t_1) Q_i^{(0)}(t) Q_k^{(0)}(t_2)$$

$$= \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) Q_j^{(0)}(t_1) Q_i^{(0)}(t) Q_k^{(0)}(t_2)$$

$$+ \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{t_1}^{t} dt_2 F_k(t_2) Q_j^{(0)}(t_1) Q_i^{(0)}(t) Q_k^{(0)}(t_2)$$

$$= \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) Q_j^{(0)}(t_1) Q_i^{(0)}(t) Q_k^{(0)}(t_2)$$

$$+ \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) Q_k^{(0)}(t_2) \times Q_i^{(0)}(t) Q_j^{(0)}(t_1). \quad (12)$$

In the last step we have inverted the order of integration in the second integral and interchanged the dummy indices i, j and the dummy times t_1, t_2. Using this result, Eq. (11) can be written in the form

$$Q_i^{(2)}(t) = \left(-\frac{1}{i\hbar}\right)^2 \sum_{jk} \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) \times [Q_k^{(0)}(t_2), [Q_j^{(0)}(t_1), Q_i^{(0)}(t)]_-]_-. \quad (13)$$

Examination of Eqs. (10) and (13) clearly indicates the general form of the nth-order term $Q_i^{(n)}(t)$ in the driven Heisenberg operator $Q_i(t)$. Thus, for example, the third-order term is

$$Q_i^{(3)}(t) = \left(-\frac{1}{i\hbar}\right)^3 \sum_{jkl} \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) \times \int_{-\infty}^{t_2} dt_3 F_l(t_3) [Q_l^{(0)}(t_3) \times [Q_k^{(0)}(t_2), [Q_j^{(0)}(t_1), Q_i^{(0)}(t)]_-]_-]_-. \quad (14)$$

This section follows the perturbation formulation given by R. Kubo.[9] However, because we are later concerned with Q operators which are intrinsically time-dependent, we choose to examine the time evolution of $Q_i(t)$ rather than of $\rho(t)$.

3. THE MACROSCOPIC RESPONSE AND DRIVEN CORRELATION MOMENTS

The first-order term in the driven response $\langle Q_i(t)\rangle$ of the thermodynamic variable corresponding to the operator Q_i is

$$\langle Q_i(t)\rangle^{(1)} = \mathrm{Tr}\, \rho^{(0)} Q_i^{(1)}(t) = -\frac{1}{i\hbar} \sum_j \int_{-\infty}^{t} dt_1 F_j(t_1) \times \langle [Q_j^{(0)}(t_1), Q_i^{(0)}(t)]_-\rangle^{(0)} \quad (15)$$

where the bracket $\langle\ \rangle^{(0)}$ denotes an expectation value with respect to the equilibrium ensemble.

Similarly, the second-order term in the response is

$$\langle Q_i(t)\rangle^{(2)} = \left(-\frac{1}{i\hbar}\right)^2 \sum_{jk} \int_{-\infty}^{t} dt_1 F_j(t_1) \int_{-\infty}^{t_1} dt_2 F_k(t_2) \times \langle [Q_k^{(0)}(t_2), [Q_j^{(0)}(t_1), Q_i^{(0)}(t)]_-]_-\rangle^{(0)}. \quad (16)$$

The form of the higher-order terms is clear from Eqs. (15) and (16).

The spontaneous fluctuations in an equilibrium ensemble are characterized by the second correlation moments in time between each pair of variables, although all higher moments are required as well for a complete description. The second equilibrium correlation moment is

$$\Psi_{ij}^{(0)}(t) = \langle \tfrac{1}{2}[Q_i, Q_j^{(0)}(t)]_+\rangle^{(0)} \quad (17)$$

where the bracket $[\ ,\ ]_+$ denotes a symmetrized operator product, or anticommutator.

A driven ensemble also exhibits fluctuations about its average motion, which in general differ from the equilibrium fluctuations. The fluctuations in a driven ensemble are characterized by

$$\langle \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle = \mathrm{Tr}\, \rho^{(0)} \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+. \quad (18)$$

Using the result (10) for $Q_i^{(1)}(t)$, the first-order term $\langle \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)}$ in the driven second moment (18) becomes

$$\langle \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)} = \tfrac{1}{2}\langle [Q_i^{(0)}(t), Q_j^{(1)}(t+\tau)]_+ + [Q_i^{(1)}(t), Q_j^{(0)}(t+\tau)]_+\rangle^{(0)}$$

$$= -\frac{1}{2i\hbar} \sum_k \left\{ \int_{-\infty}^{t+\tau} dt_1 F_k(t_1) \langle [Q_i^{(0)}(t), \times [Q_k^{(0)}(t_1), Q_j^{(0)}(t+\tau)]_-]_+\rangle^{(0)} + \int_{-\infty}^{t} dt_1 F_k(t_1) \langle [[Q_k^{(0)}(t_1), Q_i^{(0)}(t)]_- \times Q_j^{(0)}(t+\tau)]_+\rangle^{(0)} \right\}. \quad (19)$$

Upon decomposition of the first integral according to

$$\int_{-\infty}^{t+\tau} dt_1 = \int_{-\infty}^{t} dt_1 + \int_{t}^{t+\tau} dt_1,$$

[9] R. Kubo, J. Phys. Soc. Japan 12, 570 (1957).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Eq. (19) becomes

$$\langle\tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)}$$
$$=-\frac{1}{2i\hbar}\sum_k\Big\{\int_{-\infty}^{t} dt_1F_k(t_1)\langle[Q_k^{(0)}(t_1),$$
$$\times[Q_i^{(0)}(t), Q_j^{(0)}(t+\tau)]_+]_-\rangle^{(0)}$$
$$+\int_{t}^{t+\tau} dt_1F_k(t_1)\langle[Q_i^{(0)}(t),$$
$$\times[Q_k^{(0)}(t_1), Q_j^{(0)}(t+\tau)]_-]_+\rangle^{(0)}\Big\}. \quad (20)$$

The higher-order terms in the perturbation expansion of the driven second moment can be written in analogous fashion, although the expressions involved become rapidly more complicated. The second-order term is

$$\langle\tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(2)}$$
$$=\frac{1}{2}\Big(-\frac{1}{i\hbar}\Big)^2\sum_{kl}\Big\{\int_{-\infty}^{t} dt_1F_k(t_1)\int_{-\infty}^{t_1} dt_2F_l(t_2)$$
$$\times\langle[Q_l^{(0)}(t_2), [Q_k^{(0)}(t_1),$$
$$\times[Q_i^{(0)}(t), Q_j^{(0)}(t+\tau)]_+]_-]_-\rangle$$
$$+\int_{-\infty}^{t} dt_1F_k(t_1)\int_{t}^{t+\tau} dt_2F_l(t_2)$$
$$\times\langle[Q_k^{(0)}(t_1), [Q_i^{(0)}(t),$$
$$\times[Q_l^{(0)}(t_2), Q_j^{(0)}(t+\tau)]_-]_+]_-\rangle^{(0)}\Big\}. \quad (21)$$

The nth-order term in the driven response can be written directly in terms of the $(n-1)$st-order term in the driven commutator $\langle[Q_j(t_1),Q_i(t)]_-\rangle^{(n-1)}$.

$$\langle Q_i(t)\rangle^{(n)}=\frac{1}{n}\Big(-\frac{1}{i\hbar}\Big)\sum_j\int_{-\infty}^{t} dt_1F_j(t_1)$$
$$\times\langle[Q_j(t_1),Q_i(t)]_-\rangle^{(n-1)}. \quad (22)$$

For $n=1$ this expression is identical to Eq. (15). For $n=2$ it can be obtained directly from Eq. (16) and the commutator analog of Eq. (19). For any order it is a direct consequence of the iterative nature of the perturbation expansion, and furnishes a clear picture of the essential structure of the motion.

4. STEP-DRIVEN PROCESSES

The preceding two sections were concerned with the motion of a driven system for which the forces are arbitrary functions of the time. In order to illustrate the formalism in a simple manner, we also consider step-driven processes in particular.

A step-driven process is defined as one for which the generalized forces in the distant past have increased slowly from zero to some constant value. This constant force remains applied until $t=0$, at which time it is suddenly removed and the system is allowed to relax into its equilibrium configuration. For a step-driven process the first- and second-order responses reduce to

$$\langle Q_i(t)\rangle^{(1)}=-\frac{1}{i\hbar}\sum_j F_j\int_{-\infty}^{0} dt_1\langle[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-\rangle^{(0)}, \quad (23)$$

$$\langle Q_i(t)\rangle^{(2)}=\Big(-\frac{1}{i\hbar}\Big)^2\sum_{jk}F_jF_k\int_{-\infty}^{0} dt_1\int_{-\infty}^{t_1} dt_2$$
$$\times\langle[Q_k^{(0)}(t_2),[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-]_-\rangle^{(0)}. \quad (24)$$

When the indicated time integrations are performed in Eqs. (23) and (24), the contributions from the infinite time limits pose certain difficulties, which are related to the approach to equilibrium. This matter is examined in Appendix A. It is also possible to approach the question of step-driven processes from the following alternate point of view, which circumvents these difficulties. We expect the applied forces F_j to bring the system to a new equilibrium configuration at $t=0$, characterized by a density operator $\rho(0)$ having the generalized canonical form appropriate to an ensemble in contact with a set of reservoirs with constant intensive parameters F_j.

$$\rho(0)=\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jQ_j]\}/$$
$$\operatorname{Tr}\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jQ_j]\}. \quad (25)$$

At $t=0$ the interaction with the external systems is removed. Since for $t>0$ the Hamiltonian is simply $H^{(0)}$, the response $\langle Q_i(t)\rangle$ during a step-driven process is given by

$$\langle Q_i(t)\rangle=\operatorname{Tr}\rho(0)Q_i^{(0)}(t)$$
$$=\operatorname{Tr}\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jQ_j]\}Q_i^{(0)}(t)/$$
$$\operatorname{Tr}\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jQ_j]\}. \quad (26)$$

In order to expand Eq. (26), we first perform the well-known expansion of the operator

$$A(\beta)\equiv\exp\{-\beta[H^{(0)}+\epsilon H^{(1)}]\},$$

where $H^{(1)}$ denotes the perturbation Hamiltonian. $A(\beta)$ satisfies the integral equation

$$A(\beta)=\exp[-\beta H^{(0)}]$$
$$\times\Big\{1-\epsilon\int_0^{\beta} d\lambda\exp[\lambda H^{(0)}]H^{(1)}A(\lambda)\Big\}, \quad (27)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the iterative solution of which is

$$A(\beta)=\exp[-\beta H^{(0)}]\sum_{n=0}^{\infty}(-\epsilon)^n\int_0^\beta d\lambda_1 H^{(1)}(-i\hbar\lambda_1)\times\int_0^{\lambda_1}d\lambda_2 H^{(1)}(-i\hbar\lambda_2)\cdots\times\int_0^{\lambda_{n-1}}d\lambda_n H^{(1)}(-i\hbar\lambda_n) \quad (28)$$

where $H^{(1)}(-i\hbar\lambda_1)=\exp[\lambda_1 H^{(0)}]H^{(1)}\exp[-\lambda_1 H^{(0)}]$.

Replacing $\epsilon H^{(1)}$ by the perturbation Hamiltonian $\sum_j F_j Q_j$ in Eq. (28) yields the quantity appearing in the numerator of Eq. (26).

$$\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_j Q_j]\}=\exp[-\beta H^{(0)}]\sum_{n=0}^{\infty}(-1)^n\sum_{jk\cdots l}F_jF_k\cdots F_l\times\int_0^\beta d\lambda_1 Q_j^{(0)}(-i\hbar\lambda_1)\int_0^{\lambda_1}d\lambda_2 Q_k^{(0)}(-i\hbar\lambda_2)\cdots\times\int_0^{\lambda_{n-1}}d\lambda_n Q_l^{(0)}(-i\hbar\lambda_n). \quad (29)$$

The expansion of the denominator of Eq. (26) can be simplified by employing a technique, due to Nakajima,[10] which reduces all multiple temperature integrals by one order. Consider the trace of the operator $A(\beta)$ defined in the foregoing. Differentiating $\mathrm{Tr}\,A(\beta)=\mathrm{Tr}\exp\{-\beta[H^{(0)}+\epsilon H^{(1)}]\}$ with respect to ϵ, we obtain

$$\frac{\partial}{\partial\epsilon}\mathrm{Tr}\,A(\beta)=-\beta\,\mathrm{Tr}\exp\{-\beta[H^{(0)}+\epsilon H^{(1)}]\}H^{(1)}. \quad (30)$$

We now expand the quantity $\exp\{-\beta[H^{(0)}+\epsilon H^{(1)}]\}$ according to Eq. (27), integrate this expression with respect to ϵ, and substitute $\sum_j F_j Q_j$ for $\epsilon H^{(1)}$ to obtain the denominator of Eq. (25).

$$\mathrm{Tr}\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_j Q_j]\}=\exp[-\beta H^{(0)}]\Big\{1+\beta\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\sum_{j\cdots kl}F_j\cdots F_kF_l\times\int_0^\beta d\lambda_1\cdots\int_0^{\lambda_{n-2}}d\lambda_{n-1}Q_j^{(0)}(-i\hbar\lambda_1)\cdots\times Q_k^{(0)}(-i\hbar\lambda_{n-1})Q_l\Big\}. \quad (31)$$

We now substitute the expansions (29) and (31) into Eq. (26) and collect terms corresponding to each order in the perturbation. The results for the first few orders in the expansion of $Q_i(t)$ are found to be

$$\langle Q_i(t)\rangle^{(1)}=-\sum_j F_j\Big[\int_0^\beta d\lambda_1\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}-\beta\langle Q_i\rangle^{(0)}\langle Q_j\rangle^{(0)}\Big], \quad (32)$$

$$\langle Q_i(t)\rangle^{(2)}=\sum_{jk}F_jF_k\Big[\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\langle Q_j^{(0)}(-i\hbar\lambda_1)\times Q_k^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)}-\frac{\beta}{2}\int_0^\beta d\lambda_1\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k\rangle^{(0)}\langle Q_i\rangle^{(0)}\Big]+\beta\sum_j F_j\langle Q_j\rangle^{(0)}\langle Q_i(t)\rangle^{(1)}, \quad (33)$$

$$\langle Q_i(t)\rangle^{(3)}=-\sum_{jkl}F_jF_kF_l\Big[\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\int_0^{\lambda_2}d\lambda_3\times\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k^{(0)}(-i\hbar\lambda_2)\times Q_l^{(0)}(-i\hbar\lambda_3)Q_i^{(0)}(t)\rangle^{(0)}-\frac{\beta}{3}\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\times\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k^{(0)}(-i\hbar\lambda_2)Q_l\rangle^{(0)}\langle Q_i\rangle^{(0)}\Big]+\beta\sum_j F_j\langle Q_j\rangle^{(0)}\langle Q_i(t)\rangle^{(2)}-\frac{\beta}{2}\sum_{jk}F_jF_k\times\int_0^\beta d\lambda_1\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k\rangle^{(0)}\langle Q_i(t)\rangle^{(1)}. \quad (34)$$

The classical forms of the foregoing equations are easily obtained and constitute a series of thermodynamic relationships. Letting $q_j(t)$ denote the time-dependent classical variable corresponding to the Heisenberg operator $Q_j(t)$ and replacing traces by integrals $\int d\Gamma$ over phase space, the classical step-driven response is, from Eq. (26),

$$\langle q_i(t)\rangle=\int d\Gamma\rho(t)q_i=\int d\Gamma\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jq_j]\}q_i(t)\Big/\times\int d\Gamma\exp\{-\beta[H^{(0)}+\textstyle\sum_j F_jq_j]\} \quad (35)$$

[10] S. Nakajima, *Advances in Physics* (Taylor and Francis, Ltd., London, 1955), Vol. 4, p. 363.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

or

$$\langle q_i(t)\rangle = \langle \exp(-\beta \textstyle\sum_j F_j q_j) q_i(t)\rangle^{(0)} / \times \langle \exp(-\beta \textstyle\sum_j F_j q_j)\rangle^{(0)}. \quad (36)$$

Since all quantities appearing in Eq. (36) are now classical functions, the perturbation expansion can be carried out in a straightforward way. Thus, the first few order terms in the classical step-driven response $\langle q_i(t)\rangle$ are

$$\langle q_i(t)\rangle^{(1)} = -\beta \sum_j F_j [\langle q_j q_i(t)\rangle^{(0)} - \langle q_i\rangle^{(0)}\langle q_j\rangle^{(0)}], \quad (37)$$

$$\langle q_i(t)\rangle^{(2)} = \tfrac{1}{2}\beta^2 \sum_{jk} F_j F_k [\langle q_j q_k q_i(t)\rangle^{(0)} - \langle q_j q_k\rangle^{(0)}\langle q_i\rangle^{(0)}] + \beta \sum_j F_j \langle q_j\rangle^{(0)}\langle q_i(t)\rangle^{(1)}, \quad (38)$$

$$\langle q_i(t)\rangle^{(3)} = -\tfrac{1}{6}\beta^3 \sum_{jkl} F_j F_k F_l [\langle q_j q_k q_l q_i(t)\rangle^{(0)} - \langle q_j q_k q_l\rangle^{(0)}\langle q_i\rangle^{(0)}] - \tfrac{1}{2}\beta^2 \sum_{jk} F_j F_k \langle q_j q_k\rangle^{(0)}\langle q_i(t)\rangle^{(1)} + \beta \sum_j F_j \langle q_j\rangle^{(0)}\langle q_i(t)\rangle^{(2)}. \quad (39)$$

Equation (36) is the first truly thermodynamic relationship we have developed up to this point. It expresses the step-driven response $\langle q_i(t)\rangle$ in terms of the quantity $\langle \exp(-\beta \sum_j F_j q_j) q_i(t)\rangle^{(0)}$, which characterizes the spontaneous equilibrium fluctuations in an operationally significant way. In particular,

$$\langle \exp(-\beta \textstyle\sum_j (F_j q_j) q_i(t)\rangle^{(0)}$$

represents the second equilibrium correlation moment between the quantity $\exp(-\beta \sum_j F_j q_j)$ at time zero and the quantity q_i at time t.

The first-order term (37) in the expansion of Eq. (36) will be recognized as a classical form of the so-called fluctuation-dissipation theorem,[4] which relates the first-order response $\langle q_i(t)\rangle^{(1)}$ to the equilibrium second correlation moment $\langle q_j q_i(t)\rangle^{(0)}$ between the variables q_j and $q_i(t)$. We discuss the quantum-mechanical form of the fluctuation-dissipation theorem in the following three sections, considering the step-driven case specifically in Sec. 7.

Similarly, Eqs. (38), (39), etc., relate the second- and higher-order terms in the classical step-driven response $\langle q_i(t)\rangle$ to appropriate higher equilibrium fluctuation moments. The quantum-mechanical form of these relationships is presented in Sec. 13.

5. EQUILIBRIUM FLUCTUATIONS AND THE FIRST-ORDER RESPONSE

The linear theory of irreversibility is reviewed in this and the two following sections, following quite closely the formulation of R. Kubo.[9] The pattern of this development suggests the method of extension to nonlinear processes, and yields a relation between commutators and anticommutators to which we make frequent reference.

It is convenient to characterize the first-order response by the aftereffect function $\phi_{ij}^{(1)}(t)$, which is the response $\langle Q_j(t)\rangle^{(1)}$ to a δ-function force F_i applied at $t=0$. That is, by definition,

$$\langle Q_j(t)\rangle^{(1)} = \sum_i \int_{-\infty}^{t} dt_1 F_i(t_1)\phi_{ij}^{(1)}(t-t_1). \quad (40)$$

Thus, writing the equilibrium commutator in Eq. (15) in the equivalent form $\langle [Q_i, Q_j^{(0)}(t-t_1)]_-\rangle^{(0)}$, we identify

$$\phi_{ij}^{(1)}(t) = -\frac{1}{i\hbar}\langle [Q_i, Q_j^{(0)}(t)]_-\rangle^{(0)}. \quad (41)$$

The aftereffect function $\phi_{ij}^{(1)}(t)$ exhibits significant symmetry properties with respect to reversal of the time t and of an applied magnetic vector potential $\mathbf{A}$. The classical quantities q_i are assumed to be even functions of the particle velocities; explicitly indicating the dependence on $\mathbf{A}$, the operators $Q_i(\mathbf{A})$ then satisfy the relationship

$$Q_i(-\mathbf{A}) = Q_i^*(\mathbf{A}). \quad (42)$$

The unperturbed Hamiltonian $H^{(0)}(\mathbf{A})$ and its eigenfunctions also satisfy Eq. (42).

Because the response $\langle Q_j(t)\rangle^{(1)}$ must itself be real, it follows that $\phi_{ij}^{(1)}(t)$ is real.

A second property of $\phi_{ij}^{(1)}(t)$ is

$$\phi_{ij}^{(1)}(-t) = -\phi_{ji}^{(1)}(t). \quad (43)$$

Introducing the transformation $t \rightarrow -t$ in Eq. (41), we have

$$\phi_{ij}^{(1)}(-t) = -\frac{1}{i\hbar}\langle [Q_i, Q_j^{(0)}(-t)]_-\rangle^{(0)}. \quad (44)$$

The t dependence can be transferred to the operator Q_i by performing a unitary transformation with

$$\exp\{\pm i[H^{(0)}t/\hbar]\}, \text{ proving Eq. (43).}$$

$\phi_{ij}^{(1)}(t)$ is odd under reversal of time and magnetic field.

$$\phi_{ij}^{(1)}(-t; -\mathbf{A}) = -\phi_{ij}^{(1)}(t; \mathbf{A}). \quad (45)$$

According to Eq. (42) $Q_j^{(0)}(-t; -\mathbf{A}) = Q_j^{(0)*}(t; \mathbf{A})$, similarly $\rho^{(0)}(-\mathbf{A}) = \rho^{(0)*}(\mathbf{A})$, so that $\phi_{ij}^{(1)}(-t; -\mathbf{A}) = -\phi_{ij}^{(1)*}(t; \mathbf{A})$. Invoking the reality of $\phi_{ij}^{(1)}(t; \mathbf{A})$ yields the property (45).

Properties (43) and (45) also imply

$$\phi_{ij}^{(1)}(t; -\mathbf{A}) = \phi_{ji}^{(1)}(t; \mathbf{A}). \quad (46)$$

We now establish the fundamental relationship which exists between the equilibrium commutator

$$\phi_{ij}^{(1)}(t) = -(1/i\hbar)\langle [Q_i, Q_j^{(0)}(t)]_-\rangle^{(0)}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

characterizing the first-order response, and the equilibrium anticommutator $\Psi_{ij}^{(0)}(t)=\langle\frac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$, characterizing the spontaneous equilibrium fluctuations. The motivation for so doing is that the latter quantity is a true macroscopic observable of the equilibrium system, while the former is not.

Consider the equilibrium second moment $\Psi_{ij}^{(0)}(t)$. Since the analysis is carried out in the spectral representation, it is convenient to define the operators Q_i such that $\Psi_{ij}^{(0)}(t)$ has no constant component, thus avoiding the attendant δ-function singularity appearing in its Fourier transform. As discussed in Appendix A, the time-independent portion of $\Psi_{ij}^{(0)}(t)$ is

$$\lim_{t\to\infty}\Psi_{ij}^{(0)}(t)=\lim_{t\to\infty}\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$$
$$=\langle Q_i\rangle^{(0)}\langle Q_j\rangle^{(0)}. \quad (47)$$

Consequently, we assume that the operators Q_i are defined such that $\langle Q_i\rangle^{(0)}=0$.

$\Psi_{ij}^{(0)}(t)$ can be written

$$\Psi_{ij}^{(0)}(t)=\tfrac{1}{2}\langle Q_iQ_j^{(0)}(t)+Q_j^{(0)}(t)Q_i\rangle^{(0)}$$
$$=\tfrac{1}{2}\langle Q_iQ_j^{(0)}(t)+Q_i^{(0)}(-i\hbar\beta)Q_j^{(0)}(t)\rangle^{(0)}. \quad (48)$$

The second term on the right has been obtained by inserting $\exp[\pm\beta H^{(0)}]$ in front of Q_i and cyclically permuting the operators in the trace. That is,

$$\langle Q_j^{(0)}(t)Q_i\rangle^{(0)}=\mathrm{Tr}\,\rho^{(0)}Q_j^{(0)}(t)\exp[\pm\beta H^{(0)}Q_i$$
$$=\mathrm{Tr}\,\rho^{(0)}\exp[\beta H^{(0)}Q_i\exp[-\beta H^{(0)}]Q_j^{(0)}(t), \quad (49)$$

and invoking the definition (8) for $Q_i^{(0)}(-i\hbar\beta)$ gives Eq. (48). We decompose Eq. (48) into a double summation over matrix elements in the unperturbed energy representation

$$\Psi_{ij}^{(0)}(t)=\tfrac{1}{2}\sum_{lm}\rho(E_l)\{1+\exp[\beta(E_l-E_m)]\}$$
$$\times\langle E_l|Q_i|E_m\rangle\langle E_m|Q_j|E_l\rangle\exp\left[i\frac{(E_m-E_l)t}{\hbar}\right] \quad (50)$$

where $\rho(E_l)=e^{-\beta E_l}/\sum_l e^{-\beta E_l}$, and $\langle E_l|Q_i|E_m\rangle$ is the matrix element of Q_i between the eigenstates of $H^{(0)}$ having the eigenvalues E_l and E_m. In virtue of the quasi-continuous spectrum of energy eigenvalues, the double summation appearing in Eq. (50) can be replaced by a double integration over energy eigenvalues.

$$\Psi_{ij}^{(0)}(t)=\frac{1}{2}\int_{-\infty}^{\infty}dE_l\int_{-\infty}^{\infty}dE_m\rho(E_l)\eta(E_l)\eta(E_m)$$
$$\times\{1+\exp[\beta(E_l-E_m)]\}\langle E_l|Q_i|E_m\rangle$$
$$\times\langle E_m|Q_j|E_l\rangle\exp\left[i\frac{(E_m-E_l)t}{\hbar}\right] \quad (51)$$

where $\eta(E_l)$ is the energy density-of-states function.

We obtain the Fourier transform $G_{ij}^{(0)}(\omega)$ of $\Psi_{ij}^{(0)}(t)$ by introducing

$$E_m=E_l+\hbar\omega. \quad (52)$$

Thus Eq. (51) becomes

$$\Psi_{ij}^{(0)}(t)=\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$$
$$=\frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty}d\omega e^{i\omega t}G_{ij}^{(0)}(\omega) \quad (53)$$

where

$$G_{ij}^{(0)}(\omega)=\left(\frac{\pi}{2}\right)^{\frac{1}{2}}\hbar[1+\exp(-\hbar\beta\omega)]\int_{-\infty}^{\infty}dE\rho(E)$$
$$\times\eta(E)\eta(E+\hbar\omega)\langle E|Q_i|E+\hbar\omega\rangle$$
$$\times\langle E+\hbar\omega|Q_j|E\rangle; \quad (54)$$

$G_{ij}^{(0)}(\omega)$ is the spectrum of the spontaneous equilibrium fluctuations.

We obtain the Fourier transform of the aftereffect function $\phi_{ij}^{(1)}(t)$ in an analogous way. Equation (41) can be rewritten

$$\phi_{ij}^{(1)}(t)=-\frac{1}{i\hbar}\langle Q_iQ_j^{(0)}(t)-Q_j^{(0)}(t)Q_i\rangle^{(0)}$$
$$=-\frac{1}{i\hbar}\langle Q_iQ_j^{(0)}(t)-Q_i^{(0)}(-i\hbar\beta)Q_j^{(0)}(t)\rangle^{(0)}. \quad (55)$$

Decomposing the equilibrium expectation value into a double integral over matrix elements in the unperturbed energy representation and introducing the transformation (52), we obtain the result

$$\phi_{ij}^{(1)}(t)=\frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty}d\omega e^{i\omega t}L_{ij}^{(1)}(\omega) \quad (56)$$

where

$$L_{ij}^{(1)}(\omega)=(2\pi)^{\frac{1}{2}}i[1-\exp(-\hbar\beta\omega)]\int_{-\infty}^{\infty}dE\rho(E)\eta(E)$$
$$\times\eta(E+\hbar\omega)\langle E|Q_i|E+\hbar\omega\rangle\langle E+\hbar\omega|Q_j|E\rangle \quad (57)$$

is clearly the Fourier transform of $\phi_{ij}^{(1)}(t)$.

Comparison of Eqs. (54) and (57) shows that the Fourier transform $G_{ij}^{(0)}(\omega)$ of the equilibrium second moment $\Psi_{ij}^{(0)}(t)$ is related to the Fourier transform $L_{ij}^{(1)}(\omega)$ of the aftereffect function $\phi_{ij}^{(1)}(t)$ according to

$$i\omega G_{ij}^{(0)}(\omega)=E^{(1)}(\omega;\beta)L_{ij}^{(1)}(\omega) \quad (58)$$

where

$$E^{(1)}(\omega;\beta)=\frac{\hbar\omega}{2}\coth\frac{\hbar\beta\omega}{2}\underset{\beta\to0}{\longrightarrow}\frac{1}{\beta}. \quad (59)$$

The universal function $E^{(1)}(\omega;\beta)$ is uniquely quantum-mechanical in origin and corresponds to a slight

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

smearing out of the microscopic contributions to the macroscopic response at extremely high frequencies ($\gtrsim 10^{12}$ cps at room temperature). In the classical limit $\beta \to 0$, $E^{(1)}(\omega;\beta) \to (1/\beta)$ as indicated.

Equation (58) is the spectral statement of the fundamental relationship which exists between the first-order response and the spontaneous equilibrium fluctuations. It provides directly the basis for the fluctuation-dissipation theorem, several alternate forms of which have been developed.[3,4,9] We discuss these in the following two sections.

The result (58) has also been obtained by Kubo[9] using function-theoretical arguments rather than the matrix approach employed here.

6. THE ADMITTANCE AND THE FLUCTUATION-DISSIPATION THEOREM

We rephrase the results of the preceding section in the familiar terms afforded by the admittance matrix. We define $\alpha_j(\omega)$ and $\gamma_i(\omega)$ as the Fourier transforms of the first-order "current" and force, respectively,

$$\frac{d}{dt}\langle Q_j(t)\rangle^{(1)} = \langle \dot{Q}_j(t)\rangle^{(1)} = \frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty} d\omega e^{i\omega t}\alpha_j(\omega), \quad (60)$$

$$F_i(t) = \frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty} d\omega e^{i\omega t}\gamma_i(\omega). \quad (61)$$

We further define the admittance matrix elements $Y_{ij}(\omega)$ by

$$\alpha_j(\omega) = \sum_i \gamma_i(\omega) Y_{ij}(\omega) \quad (62)$$

whence, from the definition (40), it follows that

$$Y_{ij}(\omega) = i\omega\int_0^{\infty} dt e^{-i\omega t}\phi_{ij}^{(1)}(t). \quad (63)$$

By Eq. (63) the symmetry properties appropriate to $Y_{ij}(\omega)$ follow immediately from the symmetry properties of $\phi_{ij}^{(1)}(t)$. The reality of $\phi_{ij}^{(1)}(t)$ implies that the real and imaginary parts of $Y_{ij}(\omega)$ are even and odd, respectively, under the transformation $\omega \to -\omega$.

$$\left.\begin{matrix}\mathrm{Re}\\ \mathrm{Im}\end{matrix}\right\} Y_{ij}(-\omega) = \left\{\begin{matrix}+\mathrm{Re}\\ -\mathrm{Im}\end{matrix}\right\} Y_{ij}(\omega). \quad (64)$$

The symmetry property (46) of $\phi_{ij}^{(1)}(t)$ with respect to reversal of the applied magnetic field implies a corresponding symmetry of $Y_{ij}(\omega)$.

$$Y_{ij}(\omega; -\mathbf{A}) = Y_{ji}(\omega; \mathbf{A}). \quad (65)$$

Equation (65) represents the extension of the original Onsager reciprocity[1,2] to all frequency components of the admittance matrix elements.

We now rewrite the spectral relationship between the first order response and the equilibrium fluctuations in terms of the $Y_{ij}(\omega)$ by decomposing Eq. (58) into its symmetric and antisymmetric parts with respect to the indices ij.

$${}^{(s)(a)}G_{ij}^{(0)}(\omega) = \frac{E^{(1)}(\omega;\beta)}{i\omega}\tfrac{1}{2}[L_{ij}^{(1)}(\omega) \pm L_{ji}^{(1)}(\omega)] \quad (66)$$

where the superscripts (s) and (a) denote the symmetric and antisymmetric parts, respectively. However, using the time-reversal symmetry property (43) of $\phi_{ij}^{(1)}(t)$, it follows from Eq. (63) for $Y_{ij}(\omega)$ and Eq. (58) for $L_{ij}^{(1)}(\omega)$ that these quantities are related according to

$$\tfrac{1}{2}[L_{ij}^{(1)}(\omega) + L_{ji}^{(1)}(\omega)] = -\frac{2i}{(2\pi)^{\frac{1}{2}}}\frac{\mathrm{Re}^{(s)}Y_{ij}(\omega)}{\omega}, \quad (67)$$

$$\tfrac{1}{2}[L_{ij}^{(1)}(\omega) - L_{ji}^{(1)}(\omega)] = \frac{2}{(2\pi)^{\frac{1}{2}}}\frac{\mathrm{Im}^{(a)}Y_{ij}(\omega)}{\omega}. \quad (68)$$

$\mathrm{Re}^{(s)}Y_{ij}(\omega)$ is the real (symmetric) part of $Y_{ij}(\omega)$ and $\mathrm{Im}^{(a)}Y_{ij}(\omega)$ the imaginary (antisymmetric part). We note from Eq. (65) that $\mathrm{Re}^{(s)}Y_{ij}(\omega)$ and $\mathrm{Im}^{(a)}Y_{ij}(\omega)$ are even and odd, respectively, with respect to reversal of the vector potential $\mathbf{A}$.

Substituting the relations (67) and (68) into Eq. (66), we obtain the results

$${}^{(s)}G_{ij}^{(0)}(\omega) = -\left(\frac{2}{\pi}\right)^{\frac{1}{2}}E^{(1)}(\omega;\beta)\frac{\mathrm{Re}^{(s)}Y_{ij}(\omega)}{\omega^2}, \quad (69)$$

$${}^{(a)}G_{ij}^{(0)}(\omega) = -i\left(\frac{2}{\pi}\right)^{\frac{1}{2}}E^{(1)}(\omega;\beta)\frac{\mathrm{Im}^{(a)}Y_{ij}(\omega)}{\omega^2}. \quad (70)$$

Since $G_{ij}^{(0)}(\omega)$ is the spectrum of the equilibrium second moment $\langle\frac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$, the Fourier transforms of Eqs. (69) and (70) are

$${}^{(s)}\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)} = -\frac{2}{\pi}\int_0^{\infty} d\omega\cos\omega t E^{(1)}(\omega;\beta)\frac{\mathrm{Re}^{(s)}Y_{ij}(\omega)}{\omega^2}, \quad (71)$$

$${}^{(a)}\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)} = \frac{2}{\pi}\int_0^{\infty} d\omega\sin\omega t E^{(1)}(\omega;\beta)\frac{\mathrm{Im}^{(a)}Y_{ij}(\omega)}{\omega^2}. \quad (72)$$

The symmetric part ${}^{(s)}\langle\frac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$ of the equilibrium second moment with respect to ij is even with respect to reversal of the vector potential $\mathbf{A}$, while the antisymmetric part ${}^{(a)}\langle\frac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$ is an odd function of $\mathbf{A}$. Further, ${}^{(a)}\langle\frac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$ vanishes in the absence of an applied magnetic field.

Equations (69) and (70) or (71) and (72) constitute the familiar spectral statement of the fluctuation-dissipation theorem.[4] In the classical limit $\beta \to 0$ [see Eq. (59)], Eqs. (70) and (71) reduce to the familiar

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Nyquist forms

$$^{(s)}\langle q_i q_j(t)\rangle^{(0)} = -\frac{2}{\pi\beta}\int_0^\infty d\omega \cos\omega t \frac{\mathrm{Re}^{(s)}Y_{ij}(\omega)}{\omega^2}, \quad (73)$$

$$^{(a)}\langle q_i q_j(t)\rangle^{(0)} = \frac{2}{\pi\beta}\int_0^\infty d\omega \sin\omega t \frac{\mathrm{Im}^{(a)}Y_{ij}(\omega)}{\omega^2}. \quad (74)$$

If we put $t=0$ in the Nyquist relation (73), the left-hand member represents the total noise intensity. It is of interest to note that this form of the equation for $t=0$ also follows from the Kramers-Krönig or dispersion relations, together with the results of equilibrium fluctuation theory. The Kramers-Krönig formulas relate the real and imaginary parts of the admittance matrix element $Y_{ij}(\omega)$ in consequence of the general requirement of causality. In Appendix B we consider this connection between the dispersion relations and the spectral form of the fluctuation-dissipation theorem.

It is sometimes convenient to characterize the spontaneous equilibrium fluctuations in terms of a set of hypothetical intensive quantities F_i rather than the extensive quantities Q_i. These hypothetical forces are associated with the fluctuating Q_i in the same formal way as real forces are associated with the average first-order driven response. That is, by analogy with Eq. (62), the fluctuating force is so defined that the product of its Fourier transform with $Y(\omega)/i\omega$ yields the Fourier transform of the fluctuating extensive parameter.

Consider a one-dimensional system with a single force $F(t)$ and corresponding operator Q. The spectrum $\mathcal{G}^{(0)}(\omega)$ of the second moment $\langle FF(t)\rangle^{(0)}$ of the equilibrium force fluctuation is defined by

$$\langle FF(t)\rangle^{(0)} = \frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty} d\omega e^{i\omega t}\mathcal{G}^{(0)}(\omega). \quad (75)$$

Using Eq. (62), together with Eq. (69) for $G^{(0)}(\omega)$, we obtain

$$\mathcal{G}^{(0)}(\omega) = \frac{\omega^2 G^{(0)}(\omega)}{|Y(\omega)|^2} = -\left(\frac{2}{\pi}\right)^{\frac{1}{2}} E^{(1)}(\omega;\beta)\frac{\mathrm{Re}\, Y(\omega)}{|Y(\omega)|^2}$$

$$= -\left(\frac{2}{\pi}\right)^{\frac{1}{2}} E^{(1)}(\omega;\beta)\,\mathrm{Re}\, Z(\omega) \quad (76)$$

where $\mathrm{Re}\, Z(\omega) = \mathrm{Re}\, Y(\omega)/|Y(\omega)|^2$ is the real, or dissipative, part of the complex impedance function. Thus, $\langle FF(t)\rangle^{(0)}$ is given by

$$\langle FF(t)\rangle^{(0)} = -\frac{2}{\pi}\int_0^\infty d\omega \cos\omega t E^{(1)}(\omega;\beta)\mathrm{Re}\, Z(\omega) \quad (77)$$

which corresponds to the one-dimensional form of the fluctuation-disspation theorem (71) for

$$\langle \tfrac{1}{2}[Q, Q^{(0)}(t)]_+\rangle^{(0)}.$$

Similarly, it is shown that the symmetric and antisymmetric parts of the second moment $\langle F_i F_j(t)\rangle^{(0)}$ of the equilibrium force fluctuations for a multidimensional system are given by

$$^{(s)}\langle F_i F_j(t)\rangle^{(0)} = -\frac{2}{\pi}\int_0^\infty d\omega \cos\omega t E^{(1)}(\omega;\beta) \times \mathrm{Re}^{(s)}Z_{ij}(\omega), \quad (78)$$

$$^{(a)}\langle F_i F_j(t)\rangle^{(0)} = \frac{2}{\pi}\int_0^\infty d\omega \sin\omega t E^{(1)}(\omega;\beta) \times \mathrm{Im}^{(a)}Z_{ij}(\omega). \quad (79)$$

The symmetry properties of the elements $Z_{ij}(\omega)$ of the complex impedance matrix are identical to those of $Y_{ij}(\omega)$.

The fluctuation-disspation theorem of Eqs. (71) and (72) or (78) and (79), which establishes a quantitative relationship between a dissipative process and appropriate equilibrium fluctuations, can be given the following intuitive interpretation. A dissipative process can be conveniently considered to involve the interaction between the dissipative system and a source system or signal generator. As mentioned at the beginning of Sec. 2, the dissipative system is characterized by a large number of degrees of freedom and is capable of absorbing energy when acted upon by an imposed force. In equilibrium it exhibits random fluctuations of its variables.

The source system, on the other hand, which provides the imposed forces and delivers energy to the dissipative system, is characterized by relatively few degrees of freedom and a high degree of excitation. Examples of such systems might be a classical pendulum or polyatomic molecule. When isolated from the dissipative system and given some internal energy, the source system may be regarded as having a sort of internal coherence.

If the source system is now connected to the dissipative system, this internal coherence is destroyed, the periodic motion vanishes, and the energy is sapped away, until finally the source system is left with only the random disordered energy $1/\beta$ characteristic of thermal equilibrium. This loss of coherence within the source system may be regarded as being caused by the random fluctuations generated by the dissipative system and acting back upon the source system itself. The disspation therefore appears as the macroscopic consequence of the disordering effect of the random equilibrium fluctuations, and, as such, is necessarily quantitatively related to the fluctuations.

An interesting analogy is furnished by the historical development of the theory of spontaneous radiation from excited atoms. After the initial development of quantum mechanics, it was found impossible to compute the spontaneous transition probabilities for an isolated excited atom, and this dissipative process appeared to be outside the existing structure of dynamics. With the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

advent of quantum electrodynamics, however, the dissipation could be computed, and it was found that the spontaneous transitions could be consistently considered to be induced by the random fluctuations of the electromagnetic field in the vacuum. In this case, the excited atom plays the role of the source system, and the vacuum plays the role of the dissipative system.

7. THE FIRST-ORDER RESPONSE—TEMPORAL REPRESENTATION

A particularly useful temporal form of the fluctuation-dissipation theorem, due to R. Kubo,[9] is obtained by taking the Fourier transform of the basic spectral relationship (58) between $L_{ij}^{(1)}(\omega)$ and $G_{ij}^{(0)}(\omega)$. According to Eq. (56) this yields the aftereffect function $\phi_{ij}^{(1)}(t)$ in the form

$$\phi_{ij}^{(1)}(t)=\frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty}d\omega e^{i\omega t}\frac{1}{E^{(1)}(\omega;\beta)}i\omega G_{ij}^{(0)}(\omega). \quad (80)$$

Letting

$$1/E^{(1)}(\omega;\beta)=\int_{-\infty}^{\infty}dt e^{-i\omega t}\Gamma(t)$$

and noting from Eq. (53) that

$$i\omega G_{ij}^{(0)}(\omega)=[1/(2\pi)^{\frac{1}{2}}]\int_{-\infty}^{\infty}dt e^{-i\omega t}\langle\tfrac{1}{2}[Q_i,\dot{Q}_j^{(0)}(t)]_+\rangle^{(0)},$$

Eq. (80) becomes

$$\phi_{ij}^{(1)}(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega\int_{-\infty}^{\infty}dt'\Gamma(t')\times\int_{-\infty}^{\infty}dt''\langle\tfrac{1}{2}[Q_i,\dot{Q}_j^{(0)}(t'')]_+\rangle^{(0)}e^{i\omega(t-t'-t'')}. \quad (81)$$

Invoking the δ-function property of

$$\int_{-\infty}^{\infty}d\omega e^{i\omega(t-t'-t'')},$$

we obtain the result

$$\phi_{ij}^{(1)}(t)=-\frac{1}{i\hbar}\langle[Q_i,Q_j^{(0)}(t)]_-\rangle^{(0)}=\int_{-\infty}^{\infty}dt'\Gamma(t-t')\langle\tfrac{1}{2}[Q_i,\dot{Q}_j^{(0)}(t')]_+\rangle^{(0)} \quad (82)$$

where

$$\Gamma(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega e^{i\omega t}\frac{1}{E^{(1)}(\omega;\beta)}=\frac{2}{\pi\hbar}\ln\coth\frac{\pi|t|}{2\hbar\beta}\underset{\beta\to 0}{\longrightarrow}\beta\delta(t). \quad (83)$$

The evaluation of the function $\Gamma(t)$ has previously been carried out by R. Kubo,[9] and is presented in Appendix C.

Equation (82) constitutes the temporal statement of the fluctuation-dissipation theorem. Although equivalent to the spectral form of Eq. (58), it presents the basic relationship between equilibrium commutators and anticommutators in a more explicit fashion.

The result (82) can of course be substituted back into Eq. (40) for $\langle Q_j(t)\rangle^{(1)}$ to yield the first-order response directly in terms of the equilibrium correlation moment.

$$\langle Q_j(t)\rangle^{(1)}=-\sum_i\int_{\infty}^{t}dt_1F_i(t_1)\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')\times\langle\tfrac{1}{2}[\dot{Q}_i^{(0)}(t_1'),Q_j^{(0)}(t)]_+\rangle^{(0)}. \quad (84)$$

In obtaining (84) from (40) and (82), we have introduced the transformation $t_1'=t-t'$ and made use of the identity

$$\langle\tfrac{1}{2}[Q_i,\dot{Q}_j^{(0)}(t_1-t_1')]_+\rangle^{(0)}=-\langle\tfrac{1}{2}[\dot{Q}_i^{(0)}(t_1'),Q_j^{(0)}(t)]_+\rangle^{(0)}.$$

In the classical limit $\beta\to 0$, Eq. (84), in virtue of the δ-function property of $\Gamma(t)$, reduces to

$$\langle q_j(t)\rangle^{(1)}=-\beta\sum_i\int_{-\infty}^{t}dt_1F_i(t_1)\langle\dot{q}_i(t_1)q_j(t)\rangle^{(0)}. \quad (85)$$

The first-order response during a step-driven process can be obtained directly from Eq. (84) by introducing the step-function forces defined in Sec. 4.

$$\langle Q_j(t)\rangle^{(1)}=-\sum_i F_i\int_{-\infty}^{0}dt_1\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')\times\langle\tfrac{1}{2}[\dot{Q}_i^{(0)}(t_1'),Q_j^{(0)}(t)]_+\rangle^{(0)}. \quad (86)$$

Integrating by parts and putting $\langle Q_i\rangle^{(0)}=0$ gives

$$\langle Q_j(t)\rangle^{(1)}=\sum_i F_i\int_{-\infty}^{0}dt_1\int_{-\infty}^{\infty}dt_1'\frac{\partial\Gamma(t_1-t_1')}{\partial t_1'}\times\langle\tfrac{1}{2}[Q_i^{(0)}(t_1'),Q_j^{(0)}(t)]_+\rangle^{(0)} \quad (87)$$

or, performing the t_1-integration,

$$\langle Q_j(t)\rangle^{(1)}=-\sum_i F_i\int_{-\infty}^{\infty}dt_1'\Gamma(t_1')\times\langle\tfrac{1}{2}[Q_i^{(0)}(t_1'),Q_j^{(0)}(t)]_+\rangle^{(0)}. \quad (88)$$

In the classical limit $\beta\to 0$, it reduces to Eq. (37) (with $\langle q_i\rangle^{(0)}=0$).

Throughout this and the preceding two sections we have been explicitly concerned with the driven response of standard thermodynamic variables such as volume, number of particles, magnetic moment, etc. However,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

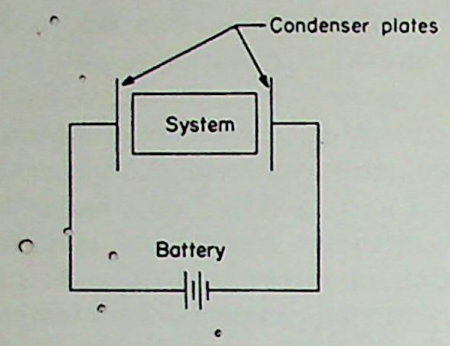

FIG. 2.

in the important case of transport processes one is interested in driven generalized currents rather than in conventional thermodynamic parameters. The special considerations required to treat currents, and particularly to treat the steady state, have been carefully discussed elsewhere.[11] Before concluding the discussion of the linear theory of irreversibility, we indicate briefly the manner of formulation of the theory in terms of driven currents.

We consider the case of electrical conduction, for example, by assuming the specific Hamiltonian

$$H(t)=H^{(0)}+\sum_{i=1}^{3}\mathcal{E}_i(t)Q_i=H^{(0)}+e\sum_{i=1}^{3}\mathcal{E}_i(t)\sum_{\mu}x_{i\mu} \quad (89)$$

where $\mathcal{E}_i(t)$ is the applied electric field in the ith direction, and $x_{i\mu}$ is the ith displacement component of μth charged particle. The component J_i of the current operator $\mathbf{J}$ is simply the time derivative of the operator Q_i.

$$J_i=\dot{Q}_i=e\sum_{\mu}\dot{x}_{i\mu}. \quad (90)$$

In our interpretation heretofore we would have visualized the Hamiltonian (89) as applying to the physical situation illustrated in Fig. 2. The field is applied to the sample by condenser plates which are *not* in physical contact with the sample. The state asymptotically approached after imposition of a step-function force is one with zero current. An alternative interpretation arises if we formally impose periodic boundary conditions on the particle wave functions in the system. A step-function applied force then leads asymptotically to a steady-state current. The formalism is essentially unchanged, but the trace of any operator implies a summation over an entirely different Hilbert space than has been implied heretofore.

The first-order current response $\langle J_j(t)\rangle^{(1)}$ is given, from Eq. (15), by

$$\langle J_j(t)\rangle^{(1)}=-\frac{1}{i\hbar}\sum_{i=1}^{3}\int_{-\infty}^{t}dt_1\mathcal{E}_i(t_1)\langle[Q_i^{(0)}(t_1),J_j^{(0)}(t)]_-\rangle^{(0)}$$

$$=-\frac{1}{i\hbar}\sum_{i=1}^{3}\int_{-\infty}^{t}dt_1\mathcal{E}_i(t_1)\,{}^{J}\phi_{ij}^{(1)}(t-t_1) \quad (91)$$

where the current after-effect function ${}^{J}\phi_{ij}^{(1)}(t)$ is

$${}^{J}\phi_{ij}^{(1)}(t)=-\frac{1}{i\hbar}\langle[Q_i,J_j^{(0)}(t)]_-\rangle^{(0)}. \quad (92)$$

The fluctuation-dissipation theorem relating the first-order current response to the second moment $\langle\frac{1}{2}[J_i,J_j^{(0)}(t)]_+\rangle^{(0)}$ of the spontaneous equilibrium current fluctuations is readily obtained using the techniques employed previously in connection with the extensive parameter displacements Q_i. The results, in the spectral and temporal representations, respectively, are

$${}^{(s)}\langle\tfrac{1}{2}[J_i,J_j^{(0)}(t)]_+\rangle^{(0)}$$

$$=-\frac{2}{\pi}\int_0^{\infty}d\omega\cos\omega tE^{(1)}(\omega;\beta)\,\mathrm{Re}\,{}^{(s)}Y_{ij}(\omega), \quad (93)$$

$${}^{(a)}\langle\tfrac{1}{2}[J_i,J_j^{(0)}(t)]_+\rangle^{(0)}$$

$$=\frac{2}{\pi}\int_0^{\infty}d\omega\sin\omega tE^{(1)}(\omega;\beta)\,\mathrm{Im}\,{}^{(a)}Y_{ij}(\omega), \quad (94)$$

$${}^{J}\phi_{ij}^{(1)}(t)=\int_{-\infty}^{\infty}dt'\Gamma(t-t')\langle\tfrac{1}{2}[J_i,J_j^{(0)}(t')]_+\rangle^{(0)}. \quad (95)$$

Equations (93) and (94) follow immediately from Eqs. (71) and (72), if we replace the operators Q_i by their time derivatives J_i, which simply removes the factor $(1/\omega)^2$ in the integrand. Similarly, Eq. (95) corresponds to Eq. (82) for $\phi_{ij}^{(1)}(t)$.

Finally, the above analysis of driven currents can be justified by another consideration, which is perhaps more physical than the artifice of periodic boundary conditions applied to the system in Fig. 2. We consider a time-dependent magnetic field $\mathcal{H}(t)$ imposed axially through a toroidal conductor, as shown in Fig. 3. The induced current in the toroid will be driven by a tangential electric field $\mathcal{E}(t)=-\dot{\mathbf{A}}(t)$, $\mathbf{A}(t)$ being the vector potential associated with $\mathcal{H}(t)$. The Hamiltonian appropriate to this situation is

$$H(t)=H^{(0)}+A(t)J \quad (96)$$

where J is the operator corresponding to the electrical current around the toroid.

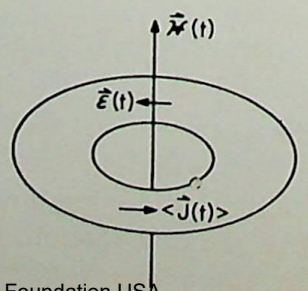

FIG. 3.

[11] See W. Kohn and J. M. Luttinger, Phys. Rev. 108, 590 (1957).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The first-order response $\langle J(t)\rangle^{(1)}$ to the perturbation $A(t)J$ is then

$$\langle J(t)\rangle^{(1)} = -\frac{1}{i\hbar}\int_{-\infty}^{t} dt_1 A(t_1)\langle[J^{(0)}(t_1), J^{(0)}(t)]_-\rangle^{(0)}. \quad (97)$$

$\langle J(t)\rangle^{(1)}$ can be rewritten in terms of the induced electric field $\mathcal{E}(t)$ by integrating Eq. (97) by parts.

$$\langle J(t)\rangle^{(1)} = -\frac{1}{i\hbar}A(t)\int_{-\infty}^{t} dt_1\langle[J^{(0)}(t_1), J^{(0)}(t)]_-\rangle^{(0)}$$

$$-\frac{1}{i\hbar}\int_{-\infty}^{t} dt_1 \mathcal{E}(t_1)\int_{-\infty}^{t_1} dt_1'\langle[J^{(0)}(t_1'), J^{(0)}(t)]_-\rangle^{(0)} \quad (98)$$

where we have let $\dot{A}(t_1) = -\mathcal{E}(t_1)$.

The term involving $\mathcal{E}(t)$ is the physically interesting one, the integrated term corresponding simply to the accumulation of magnetic field required to sustain the driving electric field. By ignoring the latter term, the physical situation is precisely that which would obtain if the process were driven by a battery placed in the circuit rather than by the magnetic field $\mathcal{H}(t)$. For this case, $\langle J(t)\rangle^{(1)}$ reduces to

$$\langle J(t)\rangle^{(1)} = -\frac{1}{i\hbar}\int_{-\infty}^{t} dt_1 \mathcal{E}(t_1)$$

$$\times\int_{-\infty}^{t_1} dt_1'\langle[J^{(0)}(t_1'), J^{(0)}(t)]_-\rangle^{(0)}. \quad (99)$$

By Eq. (90) we identify

$$Q_i^{(0)}(t_1) = \int_{-\infty}^{t_1} dt_1' J^{(0)}(t_1'). \quad (100)$$

Therefore,

$$\langle J(t)\rangle^{(1)} = -\frac{1}{i\hbar}\int_{-\infty}^{t} dt_1 \mathcal{E}(t_1)\langle[Q^{(0)}(t_1), J^{(0)}(t)]_-\rangle^{(0)} \quad (101)$$

which is identical with Eq. (91) for the case of one-dimensional electrical conduction.

8. APPLICATIONS OF THE FIRST-ORDER THEORY

Several applications of the foregoing first-order theory are now mentioned briefly.

In their original paper on the fluctuation-dissipation theorem, Callen and Welton[4] discussed the relation of that theorem to the energy density in an isotropic radiation field. The impedance of a charged particle driven by a periodic electric field exhibits a dissipative term arising from the radiation damping force. According to the fluctuation-dissipation theorem (78), this implies the existence of a random fluctuating electric field exerted by the vacuum on the free particle. The energy density of this fluctuating field is found to be just the familiar Planck radiation density.

Van Vliet[12] has recently employed the fluctuation-dissipation theorem to discuss the equilibrium charge carrier fluctuations in semiconducting materials. A simple admittance matrix corresponding to a linear RC network is introduced, the resistances being expressed in terms of transition rates between different groups of carrier levels. The fluctuation-dissipation theorem thereby yields the second moments of the equilibrium carrier fluctuations in terms of the thermal generation-recombination process. The charge carrier fluctuations in turn give rise to a contribution to the driven noise, to which further reference is made in Sec. 12.

In addition to the fluctuation-dissipation theorem and the spectral reciprocity, Kubo[9] points out that general proofs of certain sum rules can be obtained from irreversible thermodynamic considerations. Thus, for the case of electrical conductivity in a system of interacting particles in an applied magnetic field, he finds that the frequency integrals of $\mathrm{Re}^{(s)}Y_{ij}(\omega)$ and $\omega\,\mathrm{Im}^{(a)}Y_{ij}(\omega)$ are given by

$$\frac{2}{\pi}\int_0^{\infty} d\omega\,\mathrm{Re}^{(s)}Y_{ij}(\omega) = \sum_r \frac{e^2 n_r}{m_r}\delta_{ij}, \quad (102)$$

$$\frac{2}{\pi}\int_0^{\infty} d\omega\,\omega\,\mathrm{Im}^{(a)}Y_{ij}(\omega) = \sum_r \frac{e_r^3 n_r}{m_r^2 c}\mathcal{H}_z. \quad (103)$$

n_r, m_r, and e_r are the number, mass, and charge, respectively, of the rth type of particle, and $\mathcal{H}_z$ is the z-directed applied magnetic field. Analogous sum rules can be derived for the magnetic susceptibility matrix.

H. Mori[13] has applied the fluctuation-disspation theorem to the analysis of transport processes in fluids. The coupling between the slow macroscopic relaxation of the system and the rapid microscopic fluctuations is shown to be responsible for the dissipation. Thus, the coefficients of viscosity, thermal conductivity, and diffusion can be computed in terms of the equilibrium fluctuations of the thermodynamic fluxes.

9. THE SECOND-ORDER RESPONSE IN A GENERAL PROCESS

In Secs. 5 through 8 the first-order theory of irreversible thermodynamics was reviewed, showing the relationship of $\langle Q_i(t)\rangle^{(1)}$ to the equilibrium fluctuations. Sections 9 through 14 are devoted to an extension of the fluctuation-dissipation concept to the driven second moment $\langle\frac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle$ and to the second- and higher-order terms in the driven response $\langle Q_i(t)\rangle$. A number of interrelationships among these quantities and the equilibrium fluctuations are established.

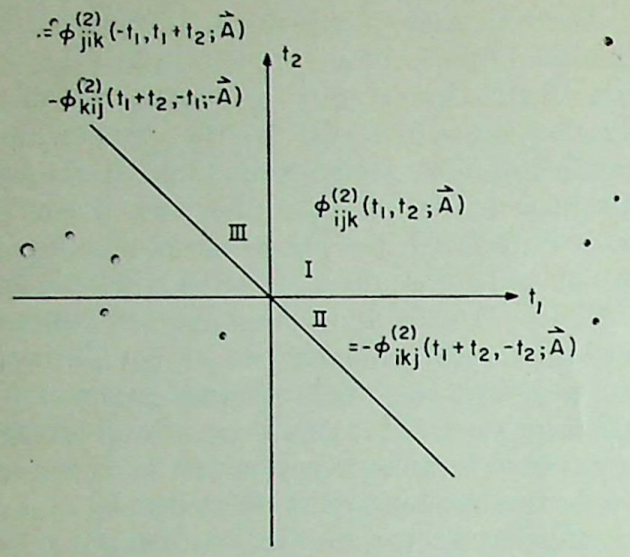

FIG. 4.

Consider the second-order response $\langle Q_i(t)\rangle^{(2)}$. From Eq. (16),

$$\langle Q_i(t)\rangle^{(2)}=\frac{1}{2}\left(-\frac{1}{i\hbar}\right)^2\sum_{jk}\Big\{\int_{-\infty}^{t}dt_1F_j(t_1)\int_{-\infty}^{t_1}dt_2F_k(t_2)$$
$$\times\langle[[Q_k^{(0)}(t_2),[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-]_-]_-\rangle^{(0)}$$
$$+\int_{-\infty}^{t}dt_1F_j(t_1)\int_{t_1}^{t}dt_2F_k(tz)\langle[[Q_j^{(0)}(t_1),$$
$$\times[Q_k^{(0)}(t_2),Q_i^{(0)}(t)]_-]_-]_-\rangle^{(0)}\Big\} \quad (104)$$

where we have inverted the order of integration in the second term. The second-order after-effect function $\phi_{ijk}^{(2)}(t_1,t_2)$ is defined by rewriting Eq. (104) as

$$\langle Q_i(t)\rangle^{(2)}=\frac{1}{2}\sum_{jk}\Big\{\int_{-\infty}^{t}dt_1F_j(t_1)\int_{-\infty}^{t_1}dt_2F_k(t_2)$$
$$\times\phi_{kji}^{(2)}(t_1-t_2,\,t-t_1)$$
$$+\int_{-\infty}^{t}dt_1F_j(t_1)\int_{t_1}^{t}dt_2F_k(t_2)$$
$$\times\phi_{jki}^{(2)}(t_2-t_1,\,t-t_2)\Big\} \quad (105)$$

whence

$$\phi_{ijk}^{(2)}(t_1,t_2)$$
$$=\left(-\frac{1}{i\hbar}\right)^2\langle[Q_i,[Q_j^{(0)}(t_1),\,Q_k^{(0)}(t_1+t_2)]_-]_-\rangle^{(0)}. \quad (106)$$

$\phi_{ijk}^{(2)}(\tau;\,t-\tau)$ is the response $\langle Q_k(t)\rangle^{(2)}$ at time $t(>0)$ to a δ-function force F_i applied at time zero, and a δ-function force F_j applied at time $\tau(>0)$. Consequently, the first term in Eq. (105) characterizes the contribution to $\langle Q_i(t)\rangle^{(2)}$ arising from the application of $F_k(t_2)$ prior to $F_j(t_1)$, while the second term characterizes the contribution arising from the application of $F_k(t_2)$ subsequent to $F_j(t_1)$.

Although Eq. (105) defines $\phi_{ijk}^{(2)}(t_1,t_2)$ only for positive t_1 and t_2, we accept Eq. (106) as the formal definition of $\phi_{ijk}^{(2)}(t_1,t_2)$ for arbitrary values of t_1 and t_2. The symmetry properties of $\phi_{ijk}^{(2)}(t_1,t_2)$ permit us to evaluate this function for arbitrary times in terms of its measured values for positive times.

We first observe that $\phi_{ijk}^{(2)}(t_1,t_2)$ is invariant with respect to simultaneous reversal of all times and the applied magnetic vector potential $\mathbf{A}$, the argument being identical to that given below Eq. (45),

$$\phi_{ijk}^{(2)}(-t_1,\,-t_2;\,-\mathbf{A})=\phi_{ijk}^{(2)}(t_1,t_2;\,\mathbf{A}). \quad (107)$$

Further, $\phi_{ijk}^{(2)}(t_1,t_2)$ can be written in either of the following forms.

$$\phi_{ijk}^{(2)}(t_1,t_2)=\left(-\frac{1}{i\hbar}\right)^2\{-\langle[Q_j^{(0)}(t_1),$$
$$\times[Q_k^{(0)}(t_1+t_2),\,Q_i]_\mp]_\mp\rangle^{(0)}$$
$$+\langle[[Q_i,\,Q_j^{(0)}(t_1)]_\mp,$$
$$\times Q_k^{(0)}(t_1+t_2)]_\mp\rangle^{(0)}\}. \quad (108)$$

These forms follow by writing out all terms in the double commutator of Eq. (106) and appropriately regrouping. Consider the double commutator form of Eq. (108), which states that

$$\phi_{ijk}^{(2)}(t_1,t_2)+\phi_{jki}^{(2)}(t_2,\,-t_1-t_2)$$
$$+\phi_{kij}^{(2)}(-t_1-t_2,\,t_1)=0. \quad (109)$$

This cyclic relationship corresponds to Eq. (43) for $\phi_{ij}^{(1)}(t)$.

We now return to our observation that the symmetries (107) and (109) permit us to evaluate $\phi_{ijk}^{(2)}(t_1,t_2)$ for arbitrary times from its measured value for positive times. Consider the t_1t_2 plane shown in Fig. 4, which we have divided into sectors. The value of $\phi_{ijk}^{(2)}(t_1,t_2;\,\mathbf{A})$ in sector I is obtained by direct measurement.

The value in sector II (for which $t_1\gtrless -t_2>0$) is obtained by noting that

$$\phi_{ijk}^{(2)}(t_1,t_2;\,\mathbf{A})=-\phi_{ijk}^{(2)}(t_1+t_2;\,-t_2;\,\mathbf{A}).$$

Sector III is determined by rewriting Eq. (109), interchanging the indice ik in the second term and reversing the vector potential $\mathbf{A}$ in the third term.

$$\phi_{ijk}^{(2)}(t_1,t_2;\,\mathbf{A})-\phi_{jik}^{(2)}(-t_1,\,t_1+t_2;\,\mathbf{A})$$
$$+\phi_{kij}^{(2)}(t_1+t_2,\,-t_1;\,-\mathbf{A})=0. \quad (110)$$

Then for $t_2>-t_1>0$ the second and third terms are measurable, thereby determining the value of the first term in sector IV.

Equation (107) reflects the known values into the remaining half-plane.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

We now discuss the relationship which exists between $\phi_{ijk}^{(2)}(t_1,t_2)$ and the equilibrium fluctuations. Consider the form of Eq. (108), for $\phi_{ijk}^{(2)}(t_1,t_2)$, involving the double anticommutators. This can be rewritten

$$\phi_{ijk}^{(2)}(t_1,t_2)=4\left(-\frac{1}{i\hbar}\right)^2[\Psi_{kij}^{(0)}(-t_1-t_2,t_1) - \Psi_{jki}^{(0)}(t_2,-t_1-t_2)] \quad (111)$$

where

$$\Psi_{ijk}^{(0)}(t_1,t_2)=\tfrac{1}{4}\langle[Q_i,[Q_j^{(0)}(t_1),Q_k^{(0)}(t_1+t_2)]_+]_+\rangle^{(0)}. \quad (112)$$

Since $\Psi_{ijk}^{(0)}(t_1,t_2)$ is the equilibrium expectation value of a symmetrized product of the operators Q_i, $Q_j^{(0)}(t_1)$, and $Q_k^{(0)}(t_1+t_2)$, it is a third correlation moment among the equilibrium fluctuations of the variables corresponding to these operators.

However, referring back to Eq. (108) to identify the two third equilibrium correlation moments in Eq. (111), we see that each involve precisely the same operators at precisely the same times, although the order of symmetrization is different! The two distinct third moments correspond in principle to different ways of measuring the correlation, as can be seen from the following general considerations.

Since there is only one way of symmetrizing a product of two non-commuting operators, it is possible to write a unique quantum-mechanical expression for the second equilibrium correlation moment [see Eq. (17)]. However, quantum mechanics furnishes no such unique *a priori* prescription for symmetrizing a product of three (or more) operators.[14] Thus, for example, in Eq. (112) we introduced the equilibrium symmetrized quantity $\Psi_{ijk}^{(0)}(t_1,t_2)$ containing four permutations of the operator product $Q_iQ_j^{(0)}(t_1)Q_k^{(0)}(t_1,t_2)$, while we can also construct the fully symmetrized form $\bar{\Psi}_{ijk}^{(0)}(t_1,t_2)$ containing all six permutations.

$$\begin{aligned}\bar{\Psi}_{ijk}^{(0)}(t_1,t_2) &= \tfrac{1}{6}\langle Q_iQ_j^{(0)}(t_1)Q_k^{(0)}(t_1+t_2) \\ &\quad + Q_j^{(0)}(t_1)Q_k^{(0)}(t_1+t_2)Q_i \\ &\quad + Q_k^{(0)}(t_1+t_2)Q_iQ_j^{(0)}(t_1)\rangle^{(0)} \\ &\quad + (\text{complex conjugate}). \end{aligned} \quad (113)$$

Each possible symmetrized arrangement corresponds to some particular experimental measurement. Consider an experiment in which three detectors monitor the variables Q_i, Q_j, and Q_k, and feed their signals into a counter. Appropriate time delay circuits are inserted between the Q_i and Q_j detectors and the counter such that the counter makes a single measurement of the desired product. Since all three signals are handled in a completely symmetrical fashion, this experiment measures the fully symmetrized operator product $\bar{\Psi}_{ijk}^{(0)}(t_1,t_2)$.

Alternately, suppose the Q_k signal and the delayed Q_j signal are fed into a multiplier, and the multiplied signal is fed into the counter along with the delayed Q_i signal. The counter makes a simultaneous measurement of the product of its two inputs. In this case Q_j and Q_k are treated symmetrically, as are their product and Q_i, and the experiment measures the quantity $\Psi_{ijk}^{(0)}(t_1,t_2)$ of Eq. (112).

In the classical limit (zero order in β) the two correlation moments become identical, as discussed later in Sec. 13.

Returning to Eq. (111), we see that this expression constitutes a thermodynamic relationship between the second-order response, characterized by the second-order aftereffect function $\phi_{ijk}^{(2)}(t_1,t_2)$, and the equilibrium fluctuations, characterized by the difference between the two operationally distinct third correlation moments $\Psi_{kij}^{(0)}(-t_1-t_2,t_1)$ and $\Psi_{jki}^{(0)}(t_2,-t_1-t_2)$.

10. FIRST-ORDER NOISE IN A GENERAL PROCESS

In this section we consider the first-order term $\langle[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$ in the driven second moment, establishing its relationship to the equilibrium fluctuations. The relationship between the first-order driven noise and the second-order response is also discussed.

The relationship of the first-order driven second moment to the equilibrium fluctuations is conveniently approached using Eq. (20) for $\langle\frac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$. The quantity

$$-(1/2i\hbar)\langle[Q_k^{(0)}(t_1),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_-\rangle^{(0)}$$

appearing in the first term of Eq. (20) is the noise response $\langle\frac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$ to an applied force $F_k(t)=\delta(t-t_1)$, $t_1<t<t+\tau$. As such, it characterizes the noise contribution arising from the application of $F_k(t_1)$ prior to time t. This noise response function can be readily symmetrized and is the quantity of primary physical interest.

On the other hand, the quantity

$$-(1/2i\hbar)\langle[Q_i^{(0)}(t),[Q_k^{(0)}(t_1),Q_j^{(0)}(t+\tau)]_-]_+\rangle^{(0)}$$

appearing in the second term of Eq. (20) is the noise response to the force $F_k(t)=\delta(t-t_1)$, $t<t_1<t+\tau$. As such it characterizes the noise contribution arising from the application of $F_k(t_1)$ in the time interval t to $t+\tau$, during which the noise is being measured. We denote this function by $\theta_{ikj}^{(1)}(t_1-t,t+\tau-t_1)$. Thus,

$$\theta_{ijk}^{(1)}(t_1,t_2) = -\frac{1}{2i\hbar}\langle[Q_i,[Q_j^{(0)}(t_1),Q_k^{(0)}(t_1+t_2)]_-]_+\rangle^{(0)}. \quad (114)$$

As we shall see, $\theta_{ijk}^{(1)}(t_1,t_2)$ is not of particular physical interest; we discuss it briefly at the end of this section in connection with the second-order response.

The first equilibrium expectation value appearing on the right-hand side of Eq. (20) can be symmetrized by

[14] J. R. Shewell, Am. J. Phys. 27, 16 (1959).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

invoking the basic relationship (82) between commutators and anticommutators. Replacing t by $(t-t_1)$ and introducing the transformation $t_1'=t-t'$ gives Eq. (82) in the form

$$-\frac{1}{i\hbar}\langle[Q_k^{(0)}(t_1),Q_i^{(0)}(t)]_-\rangle^{(0)}$$

$$=-\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')\langle\tfrac{1}{2}[\dot{Q}_k^{(0)}(t_1'),Q_i^{(0)}(t)]_+\rangle^{(0)}. \quad (115)$$

If we replace the operator Q_i by the anticommutator $\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+$, this becomes

$$-\frac{1}{2i\hbar}\langle[Q_k^{(0)}(t_1),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_-\rangle^{(0)}$$

$$=-\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),$$
$$\times[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}. \quad (116)$$

The result (116) can be substituted directly into Eq. (20), along with the definition (114) of $\theta_{ijt}^{(1)}(t_1,t_2)$, to yield the first-order driven noise in the form

$$\langle\tfrac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$$

$$=-\sum_k\int_{-\infty}^{t}dt_1F_k(t_1)\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')$$
$$\times\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}$$
$$+\sum_k\int_t^{t+\tau}dt_1F_k(t_1)\theta_{ikj}^{(1)}(t_1-t,t+\tau-t_1). \quad (117)$$

As discussed in the preceding section, the symmetrized equilibrium expectation value

$$\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}$$

is one macroscopically observable form of the third correlation moment among the spontaneous equilibrium fluctuations of the variables corresponding to the operators $\dot{Q}_k^{(0)}(t_1')$, $Q_i^{(0)}(t)$, and $Q_j^{(0)}(t+\tau)$.

A thermodynamic relationship between the intensity of the first-order driven noise and the equilibrium fluctuations follows immediately from Eq. (117). Letting $\tau=0$, the second term in Eq. (117) vanishes, leaving

$$\langle\tfrac{1}{2}[Q_i(t),Q_j(t)]_+\rangle^{(1)}$$

$$=-\sum_k\int_{-\infty}^{t}dt_1F_k(t_1)\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')$$
$$\times\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t)]_+]_+\rangle^{(0)}. \quad (118)$$

Equation (118) expresses the first-order driven noise intensity $\langle\frac{1}{2}[Q_i(t),Q_j(t)]_+\rangle^{(1)}$ in terms of the equilibrium third fluctuation moment

$$\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t)]_+]_+\rangle^{(0)}.$$

Returning to the more general quantity

$$\langle\tfrac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)},$$

for most purposes one is interested in measuring this driven noise only for processes in which the imposed forces are slowly varying over the time interval during which the noise is being measured. We therefore assume that $F_k(t_1)\simeq$constant$\equiv F_k$ in the interval t to $(t+\tau)$ although, of course, $F_k(t_1)$ is arbitrary for $t_1<t$. Further, we decompose $F_k(t_1)$ into two components according to

$$F_k(t_1)=F_k+\Delta F_k(t_1). \quad (119)$$

The contribution to $\langle\frac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$ arising from the time-dependent force component $\Delta F_k(t_1)$ is

$$-\sum_k\int_{-\infty}^{t}dt_1\Delta F_k(t_1)\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')$$
$$\times\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)} \quad (120)$$

since the integral $\int_t^{t+\tau}dt_1\Delta F_k(t_1)$ vanishes. It is therefore directly expressible in terms of the equilibrium fluctuations.

The contribution arising from the constant force component F_k, on the other hand, is just the first-order term in the perturbation expansion of the driven second moment with respect to a constant applied force. However, the application of a constant force F_k implies simply a change in the corresponding (equilibrium) intensive parameter associated with the system. Hence, this contribution can also be regarded as a macroscopically observable characteristic of the equilibrium system. We denote it by

$$\sum_k F_k\frac{\partial}{\partial F_k}\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)}$$

where the derivative is evaluated at $F_k=0$.

Inserting the quantities (120) and (121) into Eq. (117), we obtain the result

$$\langle\tfrac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$$

$$=\sum_k\Big\{-\int_{-\infty}^{t}dt_1\Delta F_k(t_1)\int_{-\infty}^{\infty}dt_1'\Gamma(t_1-t_1')$$
$$\times\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),[Q_i^{(0)}(t),Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}$$
$$+F_k\frac{\partial}{\partial F_k}\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)}\Big\}. \quad (122)$$

Equation (122) constitutes a thermodynamic relationship between $\langle\frac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle^{(1)}$ and the indicated

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

macroscopically observable characteristics of the equilibrium fluctuations.

We further note that $(\partial/\partial F_k)\langle\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)}$ can be re-expressed in terms of the nonlinear behavior of the system by invoking the fluctuation-dissipation theorem, Eqs. (71) and (72). In order to keep the notation simple, we consider explicitly the case of no applied magnetic field, for which $\langle\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)}$ reduces to

$$\langle\tfrac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)} = -\frac{2}{\pi}\int_0^\infty d\omega\,\cos\omega\tau E^{(1)}(\omega;\beta)\frac{\mathrm{Re}\,Y_{ij}(\omega)}{\omega^2}. \quad (123)$$

Just as $\langle\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+\rangle^{(0)}$ is a function of the applied forces F_k, $Y_{ij}(\omega)$ also in general depends upon F_k. Consequently, Eq. (122) can be written as

$$\langle\tfrac{1}{2}[Q_i(t),\,Q_j(t+\tau)]_+\rangle^{(0)} = \sum_k\Big\{-\int_{-\infty}^t dt_1\Delta F_k(t_1)\int_{-\infty}^\infty dt_1'\Gamma(t_1-t_1') \times\langle\tfrac{1}{4}[\dot{Q}_k^{(0)}(t_1'),\,[Q_i^{(0)}(t),\,Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)} - \frac{2}{\pi}\int_0^\infty d\omega\,\cos\omega\tau E^{(1)}(\omega;\beta)\frac{1}{\omega^2}\mathrm{Re}\frac{\partial Y_{ij}(\omega)}{\partial F_k}\Big\}. \quad (124)$$

The physical significance of the derivative $\partial Y_{ij}(\omega)/\partial F_k$ can be regarded as arising from the nonlinearity of the system in the following way. Most physical systems are nonlinear. Nevertheless, for sufficiently small deviations from a given "operating point" (corresponding to a constant applied force F_k) the linear approximation is adequate. As a consequence of the nonlinearity of the system, however, the admittance matrix must in general be a function of the "operating point." The quantity $\partial Y_{ij}(\omega)/\partial F_k$ specifies the first-order contribution to this dependence on F_k.

Equation (124) is an alternate thermodynamic expression for $\langle\frac{1}{2}[Q_i(t),\,Q_j(t+\tau)]_+\rangle^{(1)}$ to that given in Eq. (122), expressing the first-order driven noise in terms of the equilibrium third moment $\langle\frac{1}{4}[\dot{Q}_k^{(0)}(t_1'), \times[Q_i^{(0)}(t),\,Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}$ and the second-order response function $\partial Y_{ij}(\omega)/\partial F_k$.

In the classical limit, Eqs. (122) and (124) reduce, respectively, to

$$\langle q_i(t)q_j(t+\tau)\rangle^{(1)} = \sum_k\Big\{-\beta\int_{-\infty}^t dt_1\Delta F_k(t_1)\langle\dot{q}_k(t_1)q_i(t)q_j(t+\tau)\rangle^{(0)} + F_k\frac{\partial}{\partial F_k}\langle q_iq_j(\tau)\rangle^{(0)}\Big\}, \quad (125)$$

$$\langle q_i(t)q_j(t+\tau)\rangle^{(1)} = \sum_k\Big\{-\beta\int_{-\infty}^t dt_1\Delta F_k(t_1)\langle\dot{q}_k(t_1)q_i(t)q_j(t+\tau)\rangle^{(0)} - \frac{2}{\pi\beta}F_k\int_0^\infty d\omega\,\cos\omega\tau\frac{1}{\omega^2}\mathrm{Re}\frac{\partial Y_{ij}(\omega)}{\partial F_k}\Big\}. \quad (126)$$

We return finally to a brief discussion of the relationship of the noise response function $\theta_{ijk}^{(1)}(t_1,t_2)$, defined in Eq. (114), to the second-order response. This relationship also stems from the basic relationship between equilibrium commutators and anticommutators given in Eq. (82). Replacing the operator Q_j in Eq. (82) by the commutator $-(1/i\hbar)[Q_j,Q_k^{(0)}(t_2)]_-$ and noting Eqs. (106) and (114) for $\phi_{ijk}^{(2)}(t_1,t_2)$ and $\theta_{ijk}^{(1)}(t_1,t_2)$, respectively, we find that

$$\phi_{ijk}^{(2)}(t_1,t_2) = \int_{-\infty}^\infty dt_1'\Gamma(t_1-t_1')\frac{\partial}{\partial t_1'}\theta_{ijk}^{(1)}(t_1',t_2). \quad (127)$$

The spectral form of Eq. (127) is found to be

$$\theta_{ijk}^{(1)}(t_1,t_2) = \frac{1}{2\pi}\int_{-\infty}^\infty d\omega_1\int_{-\infty}^\infty d\omega_2 e^{i\omega_1t_1}e^{i\omega_2t_2} \times E^{(1)}(\omega;\beta)\frac{L_{ijk}^{(2)}(\omega_1,\omega_2)}{i\omega_1} \quad (128)$$

where $L_{ijk}^{(2)}(\omega_1,\omega_2)$ is the double Fourier transforms of $\phi_{ijk}^{(2)}(t_1,t_2)$ defined by

$$\phi_{ijk}^{(2)}(t_1,t_2) = \frac{1}{2\pi}\int_{-\infty}^\infty d\omega_1\int_{-\infty}^\infty d\omega_2 e^{i\omega_1t_1}e^{i\omega_2t_2} \times L_{ijk}^{(2)}(\omega_1,\omega_2). \quad (129)$$

Equations (128) and (129) have the following formal implications. Using Eq. (114) for $\theta_{ijk}^{(1)}(t_1,t_2)$, Eq. (19) for $\langle\frac{1}{2}[Q_i(t),\,Q_j(t+\tau)]_+\rangle^{(1)}$ can be written in the form

$$\langle\tfrac{1}{2}[Q_i(t),\,Q_j(t+\tau)]_+\rangle^{(1)} = \sum_k\Big\{\int_{-\infty}^t dt_1F_k(t_1)\theta_{jki}^{(1)}(t_1-t-\tau,\,t-t_1) + \int_{-\infty}^{t+\tau} dt_1F_k(t_1)\theta_{ikj}^{(1)}(t_1-t,\,t+\tau-t_1)\Big\}. \quad (130)$$

Since Eqs. (127) and (128) express the function $\theta_{ijk}^{(1)}(t_1,t_2)$ in terms of the macroscopically observable second-order aftereffect function $\phi_{ijk}^{(2)}(t_1,t_2)$, Eq. (130) permits us to compute $\langle\frac{1}{2}[Q_i(t),\,Q_j(t+\tau)]_+\rangle^{(0)}$ from suitable measurements of the second-order response.

11. FLUCTUATION SYMMETRY

In the preceding two sections we have established the basic interrelationship among the second-order response,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the first-order second moment, and the equilibrium third moment.

In order better to appreciate this basic interrelationship, it is of interest to examine its consistency from the point of view of symmetry. For this purpose it is convenient to represent the response $\langle Q_i(t)\rangle$ to a set of applied forces $F_j(t)$ by the symbolic expansion

$$\langle Q_i(t)\rangle = \chi_i^{(0)} + \sum_j \mathfrak{F}_j \chi_{ji}^{(0)} + \tfrac{1}{2}\sum_{jk} \mathfrak{F}_j \mathfrak{F}_k \chi_{jki}^{(2)} + \cdots . \quad (131)$$

The response functions χ are suitable combinations of the aftereffect functions defined previously, while the $\mathfrak{F}_j$ are integral operators, linear functionals of the forces $F_j(t)$ acting on the χ's. $\chi_i^{(0)}$ denotes the equilibrium expectation value $\langle Q_i\rangle^{(0)}$. Similarly, the driven second moment $\langle \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle$ can be represented by the expansion

$$\langle \tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle = \xi_{ij}^{(0)} + \sum_k \mathfrak{F}_k' \xi_{kij}^{(1)} + \tfrac{1}{2}\sum_{kl} \mathfrak{F}_k' \mathfrak{F}_l' \xi_{klij} + \cdots \quad (132)$$

where the ξ are suitable noise response functions, and the $\mathfrak{F}_k'$ are appropriate integral operators.

The physical symmetry of many systems is such that reversal of all forces simply reverses all responses $\langle Q_i(t)\rangle - \langle Q_i\rangle^{(0)}$. For such systems only the odd terms in Eq. (131), and only the even terms in Eq. (132) can exist.

The physical symmetry referred to above also has obvious implications for the equilibrium fluctuations. Consider particularly the third equilibrium correlation moment $\langle q_i q_j(t_1) q_k(t_2)\rangle^{(0)}$. This moment is defined in terms of an integral involving the equilibrium joint probability distribution $W_3^{(0)}(q_i; q_j,t_1; q_k,t_2)$. For many systems the physical symmetry implies that this joint probability distribution is unchanged if each of the q's is replaced by its negative. For such a "fluctuation-symmetric" system, all odd equilibrium correlation moments vanish.

The relations which were proven among the second-order response, the first-order noise, and the equilibrium third moments indicate that the physical symmetries referred to in the two preceding paragraphs are equivalent, as we might intuitively expect. A system which is fluctuation-symmetric, with no odd equilibrium moments, exhibits no second-order response, and no first-order noise.

A homogeneous system, symmetric under spatial inversion, is fluctuation-symmetric with respect to its transport properties. In such systems, electron, phonon, or other currents can exhibit no first-order noise.

With fluctuation-symmetric systems, it is necessary to go to second order to obtain a contribution to the driven noise. Such second-order driven noise can be appreciable in magnitude, and, in fact, is easily observed in semiconductors. By analogy with Eqs. (111), (124), and (127), the second-order noise may be presumed to depend generally in some complicated way upon the third-order response and the equilibrium fourth moment. In Sec. 12, we give a limited discussion of one contribution to second-order noise.

On the other hand, there are many systems which do not obey fluctuation-symmetry and which therefore may exhibit first-order driven noise. Rectifiers, for example, because of their pronounced asymmetry with respect to current flow, necessarily possess significant equilibrium third moments.

Finally, it is possible for a system to be fluctuation-symmetric with respect to some of its variables but not with respect to others. Thus, for example, a p-n junction is fluctuation-symmetric with respect to current in the plane of the junction but fluctuation-asymmetric with respect to current perpendicular to this plane. Another example would be a bulk solid, which we have previously mentioned as being fluctuation-symmetric with respect to its transport properties. Such a system would not in general be fluctuation symmetric with respect to its thermodynamic extensive variables such as energy, volume, or the number of particles in the conduction band.

12. SECOND-ORDER DRIVEN NOISE

Although we do not undertake a complete discussion of the second-order noise in this paper, it is of interest to indicate how the general theory would apply in a specific physical situation. As an example, we consider the steady-state thermal generation-recombination noise in semiconductors.

We consider explicitly the second-order driven current noise $\langle \tfrac{1}{2}[J_i(t), J_j(t+\tau)]_+\rangle^{(2)}$. In accordance with the recipe developed in Sec. 3 for computing driven second moments in terms of the equilibrium system, we have that

$$\begin{aligned}\langle \tfrac{1}{2}[J_i(t), J_j(t+\tau)]_+\rangle^{(2)} &= \tfrac{1}{2}\{\langle [J_i^{(0)}(t), J_j^{(2)}(t+\tau)]_+\rangle^{(0)} \\ &\quad + \langle [J_i^{(1)}(t), J_j^{(1)}(t+\tau)]_+\rangle^{(0)} \\ &\quad + \langle [J_i^{(2)}(t), J_j^{(0)}(t+\tau)]_+\rangle^{(0)}\}. \end{aligned} \quad (133)$$

Although the first and third terms also contribute to $\langle \tfrac{1}{2}[J_i(t), J_j(t+\tau)]_+\rangle^{(2)}$, we focus attention on the term $\langle \tfrac{1}{2}[J_i^{(1)}(t), J_j^{(1)}(t+\tau)]_+\rangle^{(0)}$, which is subject to clear physical interpretation.

The first-order driven current operator $J_i^{(1)}(t)$ is obtained in accordance with the discussion at the end of Sec. 7.

$$J_i^{(1)}(t) = -\frac{1}{i\hbar}\sum_k \int_{-\infty}^{t} dt_1 \mathcal{E}_k(t_1)[Q_k^{(0)}(t_1), J_i^{(0)}(t)]_-. \quad (134)$$

In the steady state, the electric field $\mathcal{E}_k(t)$ is constant,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and Eq. (134) reduces to

$$J_i^{(1)}(t)=-\frac{1}{ih}\sum_k \mathcal{E}_k \exp\left[i\frac{H^{(0)}t}{\hbar}\right] \times\int_{-\infty}^{0} dt_1[Q_k^{(0)}(t_1),J_i]_- \exp\left[-i\frac{H^{(0)}t}{\hbar}\right] \quad (135)$$

where we have let $t_1'=t-t_1$ and extracted the resulting t dependence of the commutator as indicated.

We define the unperturbed Heisenberg operator $\sigma_{ki}^{(0)}(t)$ corresponding to the kith element of the conductivity matrix by rewriting Eq. (135) as

$$J_i^{(1)}(t)=\sum_k \mathcal{E}_k\sigma_{ki}^{(0)}(t) \quad (136)$$

whence

$$\sigma_{ki}^{(0)}(t)=-\frac{1}{ih}\exp\left[i\frac{H^{(0)}t}{\hbar}\right] \times\int_{-\infty}^{0} dt_1[Q_k^{(0)}(t),J_i]_- \exp\left[-i\frac{H^{(0)}t}{\hbar}\right]. \quad (137)$$

Using Eq. (136) for $J_i^{(1)}(t)$, the contribution $\langle\frac{1}{2}[J_i^{(1)}(t), J_j^{(1)}(t+\tau)]_+\rangle^{(0)}$ to the second-order steady-state current noise becomes

$$\langle\tfrac{1}{2}[J_i^{(1)},J_j^{(1)}(\tau)]_+\rangle^{(0)} =\sum_{kl}\mathcal{E}_k\mathcal{E}_l\langle\tfrac{1}{2}[\sigma_{ki},\sigma_{lj}^{(0)}(\tau)]_+\rangle^{(0)} \quad (138)$$

where we have set $t=0$ in virtue of time stationarity. The quantity $\langle\frac{1}{2}[\sigma_{ki},\sigma_{lj}^{(0)}(\tau)]_+\rangle^{(0)}$ can be interpreted as the second correlation moment between the spontaneous equilibrium fluctuations of the conductivity matrix elements σ_{ki} and $\sigma_{jl}^{(0)}(\tau)$.

The correlation function $\langle\frac{1}{2}[\sigma,\sigma^{(0)}(t)]_+\rangle^{(0)}$ is easily calculated in the case of a simple semiconductor for which the conductivity is given by $\sigma=ne^2\tau_s/m^*$,[15] where n is the equilibrium carrier concentration, m^* is the effective mass, and τ_s denotes a simple relaxation time for the scattering mechanisms. Assuming that

$$n(t)=n_0e^{-t/\tau_\beta} \quad (139)$$

where τ_β denotes a relaxation time associated with thermal charge carrier generation and recombination, the second-order term $\langle J^{(1)}J^{(1)}(t)\rangle^{(0)}$ in the steady-state current noise $\langle JJ(t)\rangle$ is

$$\langle J^{(1)}J^{(1)}(t)\rangle^{(0)}=\frac{e^4{\tau_s}^2}{m^{*2}}\langle nn(t)\rangle^{(0)}\mathcal{E}^2 =\frac{e^4{\tau_s}^2}{m^{*2}}\langle n^2\rangle^{(0)}e^{-t/\tau_\beta}\mathcal{E}^2 \quad (140)$$

which is a well-known result.[12]

[15] See for example W. Shockley, *Holes and Electrons in Semiconductors* (D. Van Nostrand Company, Inc., Princeton, New Jersey, 1950).

There exist in general other contributions to the second-order steady-state noise, as can be seen from Eq. (133). Here we have sought only to establish the connection of the general formalism with the usual model treatment of semiconductor noise.

13. HIGHER-ORDER STEP-DRIVEN RESPONSE

Whereas we have previously shown that the second-order response in a general process is characterized by the *difference* of two equilibrium third moments, the classical result of Eq. (38) suggests the possibility of establishing a more conventional quantum relationship in the case of step-driven processes. Although measurement of two distinct equilibrium third moments is still required to determine the second-order step-driven response, we shall find that for this simple class of processes the relationship is in close formal analogy to the first-order fluctuation-dissipation theorem. Further, the uniquely quantum-mechanical effects are more easily visualized in this case.

It is convenient to consider $\langle Q_i(t)\rangle^{(2)}$ as given in the form of Eq. (33). Rewriting this expression so as to indicate explicitly both contributions from a given pair of forces F_j, F_k, and assuming that $\langle Q_i\rangle^{(0)}=0$,

$$\langle Q_i(t)\rangle^{(2)}=\tfrac{1}{2}\sum_{jk}F_jF_k\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2 \times[\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)} +\langle Q_k^{(0)}(-i\hbar\lambda_1)Q_j^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)}]. \quad (141)$$

Inserting $\exp[\pm\beta H^{(0)}]$ in front of the operator $Q_i^{(0)}(t)$ and permuting the operators cyclicly, the integrand of the second term in Eq. (141) can be rewritten

$$\langle Q_k^{(0)}(-i\hbar\lambda_1)Q_j^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)} =\langle Q_i^{(0)}(t)Q_k^{(0)}(-i\hbar\lambda_1+i\hbar\beta)Q_j^{(0)} \times(-i\hbar\lambda_2+i\hbar\beta)\rangle^{(0)}. \quad (142)$$

Thus, inverting the order of integration, and making the successive transformations $\lambda_2'=\beta-\lambda_1$, $\lambda_1'=\beta-\lambda_2$,

$$\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\langle Q_k^{(0)}(-i\hbar\lambda_1)Q_j^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)} =\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\langle Q_i^{(0)}(t)Q_k^{(0)}(+i\hbar\lambda_2) \times Q_j^{(0)}(+i\hbar\lambda_1)\rangle^{(0)}. \quad (143)$$

Inserting (143) into Eq. (141), we thereby obtain $\langle Q_i(t)\rangle^{(2)}$ in the form

$$\langle Q_i(t)\rangle^{(2)}=\tfrac{1}{2}\sum_{jk}F_jF_k\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2 \times[\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_k^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)} +\langle Q_i^{(0)}(t)Q_k^{(0)}(i\hbar\lambda_2)Q_j^{(0)}(i\hbar\lambda_1)\rangle^{(0)}]. \quad (144)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

It is further convenient to define the second-order step-response function $\Phi_{jki}^{(2)}(t)$ by rewriting Eq. (144) as

$$\langle Q_i(t)\rangle^{(2)}=\tfrac{1}{2}\sum_{jk}F_jF_k\Phi_{jki}^{(2)}(t)$$

whence

$$\Phi_{jki}^{(2)}(t)=\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2[\langle Q_j^{(0)}(-i\hbar\lambda_1)\times Q_k^{(0)}(-i\hbar\lambda_2)Q_i^{(0)}(t)\rangle^{(0)}+(\text{c.c.})]. \quad (146)$$

The notation (c.c.) is used to indicate the complex conjugate of the first term. $\Phi_{jki}^{(2)}(t)$ represents the second-order response to unit step-function forces F_j and F_k.

We now proceed to analyze $\Phi_{jki}^{(2)}(t)$ by decomposing the equilibrium expectation values appearing in Eq. (146) into appropriate summations over matrix elements in the unperturbed energy representation. This technique is similar to that employed in Sec. 5 in connection with $\phi_{ij}^{(1)}(t)$, and yields

$$\Phi_{jki}^{(2)}(t)=\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\sum_{lmn}\rho(E_l)\langle E_l|Q_j|E_m\rangle\times\langle E_m|Q_k|E_n\rangle\langle E_n|Q_i|E_l\rangle e^{\lambda_1(E_l-E_m)}\times e^{\lambda_2(E_m-E_n)}\exp\left[i\frac{(E_n-E_l)t}{\hbar}\right]+(\text{c.c.}) \quad (147)$$

where $\langle E_l|Q_j|E_m\rangle$ is the matrix element of Q_j between the eigenstates of $H^{(0)}$ having the energy eigenvalues E_l and E_m, and $\rho(E_l)=e^{-\beta E_l}/\sum_l e^{-\beta E_l}$.

Performing the indicated temperature integration, and replacing the triple summation by a triple integral over energy eigenvalues, this becomes

$$\Phi_{jki}^{(2)}(t)=\int_{-\infty}^{\infty}dE_l\int_{-\infty}^{\infty}dE_m\int_{-\infty}^{\infty}dE_n\rho(E_l)\eta(E_l)\times\eta(E_m)\eta(E_n)\left[\frac{1}{(E_l-E_n)(E_l-E_m)}-\frac{e^{\beta(E_l-E_m)}}{(E_m-E_n)(E_l-E_m)}+\frac{e^{\beta(E_l-E_n)}}{(E_m-E_n)(E_l-E_n)}\right]\times\langle E_l|Q_j|E_m\rangle\langle E_m|Q_k|E_n\rangle\langle E_n|Q_i|E_l\rangle\times\exp\left[i\frac{(E_n-E_l)t}{\hbar}\right]+(\text{c.c.}) \quad (148)$$

where $\eta(E_l)$ is the energy density-of-states function. Introducing the transformations

$$E_m=E_l+\hbar\omega_1,\quad E_n=E_l+\hbar\omega_2 \quad (149)$$

and letting $\omega_1\to-\omega_1$, $\omega_2\to-\omega_2$ in the (c.c.) term, we finally obtain $\Phi_{jki}^{(2)}(t)$ in the form

$$\Phi_{jki}^{(2)}(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega_1\int_{-\infty}^{\infty}d\omega_2e^{i\omega_2t}N_{jki}^{(2)}(\omega_1,\omega_2) \quad (150)$$

where

$$N_{jki}^{(2)}(\omega_1,\omega_2)=\left[\frac{1}{\omega_1\omega_2}+\frac{\exp(-\hbar\beta\omega_1)}{\omega_1(\omega_1-\omega_2)}+\frac{\exp(-\hbar\beta\omega_2)}{\omega_2(\omega_2-\omega_1)}\right]\times g_{jki}(\omega_1,\omega_2)+\left[\frac{1}{\omega_1\omega_2}+\frac{\exp(+\hbar\beta\omega_1)}{\omega_1(\omega_1-\omega_2)}+\frac{\exp(+\hbar\beta\omega_2)}{\omega_2(\omega_2-\omega_1)}\right]g_{jki}^*(-\omega_1,-\omega_2) \quad (151)$$

and

$$g_{jki}(\omega_1,\omega_2)=g_{ikj}^*(\omega_2,\omega_1)=2\pi\int_{-\infty}^{\infty}dE\rho(E)\eta(E)\eta(E+\hbar\omega_1)\times\eta(E+\hbar\omega_2)\langle E|Q_j|E+\hbar\omega_1\rangle\times\langle E+\hbar\omega_1|Q_k|E+\hbar\omega_2\rangle\langle E+\hbar\omega_2|Q_i|E\rangle. \quad (152)$$

In order to relate the second-order step-driven response to the equilibrium fluctuations, we undertake a similar spectral analysis of the equilibrium correlation moment of the variables corresponding to the operators Q_j, $Q_k^{(0)}(t_1)$, and $Q_i^{(0)}(t_1+t_2)$. However, as discussed at the end of Sec. 9, there exist several equally valid, operationally distinct quantum-mechanical expressions for a given equilibrium third moment. Thus, the quantity $\Psi_{jki}^{(0)}$ defined in Eq. (112) corresponds to one particular set of experimental conditions, while the fully symmetrized equilibrium form $\bar{\Psi}_{jki}^{(0)}$ defined in Eq. (113) is appropriate to a different experimental arrangement. We find, in fact, that measurement of both $\Psi_{jki}^{(0)}(t_1,t_2)$ and $\bar{\Psi}_{jki}^{(0)}(t_1,t_2)$ is required for a complete experimental determination of $\Phi_{jki}^{(2)}(t)$, except in the classical limit.

Equation (113) for $\bar{\Psi}_{jki}^{(0)}(t_1,t_2)$ is conveniently rewritten

$$\bar{\Psi}_{jki}^{(0)}(t_1,t_2)=\tfrac{1}{6}\langle Q_jQ_k^{(0)}(t_1)Q_i^{(0)}(t_1+t_2)+Q_j^{(0)}(-i\hbar\beta)Q_k^{(0)}(t_1)Q_i^{(0)}(t_1+t_2)+Q_j^{(0)}(-i\hbar\beta)Q_k^{(0)}(t_1-i\hbar\beta)\times Q_i^{(0)}(t_1+t_2)\rangle^{(0)}+(\text{c.c.}) \quad (153)$$

where we have inserted $\exp[\pm\beta H^{(0)}]$ at suitable positions in the second and third terms and permuted the operators cyclicly.

As in the case of $\Phi_{jki}^{(2)}(t)$, the quantity $\bar{\Psi}_{jki}^{(0)}(t_1,t_2)$ can be decomposed into a triple integral over matrix elements in the unperturbed energy representation. Introducing the transformations (149) and letting

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$\omega_1 \rightarrow -\omega_1$, $\omega_2 \rightarrow -\omega_2$ in the (c.c.) term, we obtain the expression

$$\Psi_{jki}^{(0)}(t_1,t_2)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega_1\int_{-\infty}^{\infty}d\omega_2 e^{i\omega_1 t_1}e^{i\omega_2 t_2} \times\bar{G}_{jki}^{(0)}(\omega_1,\omega_2) \quad (154)$$

where

$$\bar{G}_{jki}^{(0)}(\omega_1,\omega_2) =\frac{h^2}{6}\{[1+\exp(-h\beta\omega_1)+\exp(-h\beta\omega_2)] \times g_{jki}(\omega_1,\omega_2)+[1+\exp(+h\beta\omega_1) +\exp(+h\beta\omega_2)]g_{jki}^*(-\omega_1,-\omega_2)\}, \quad (155)$$

$g_{jki}(\omega_1,\omega_2)$ having been given previously in Eq. (152). $\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)$ is the double Fourier transform of the equilibrium third moment $\bar{\Psi}_{jki}^{(0)}(t_1,t_2)$.

Similar analysis of the equilibrium third moment $\Psi_{jki}^{(0)}(t_1,t_2)$ of Eq. (112) yields the result

$$\Psi_{jki}^{(0)}(t_1,t_2)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega_1\int_{-\infty}^{\infty}d\omega_2 e^{i\omega_1 t_1}e^{i\omega_2 t_2} \times G_{jki}^{(0)}(\omega_1,\omega_2) \quad (156)$$

where

$$G_{jki}^{(0)}(\omega_1,\omega_2) =\frac{h^2}{4}\{[1+\exp(-h\beta\omega_1)]g_{jki}(\omega_1,\omega_2) +[1+\exp(+h\beta\omega_1)]g_{jki}^*(-\omega_1,-\omega_2)\}. \quad (157)$$

We now discuss the relation of the second-order step-driven response to the equilibrium fluctuations using the spectral quantities $N_{jki}^{(2)}(\omega_1,\omega_2)$, $\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)$, and $G_{jki}^{(0)}(\omega_1,\omega_2)$ obtained above. In order to indicate the formal analogy of this relationship to the first-order fluctuation-dissipation theorem, it is convenient to define the functions $r_{jki}^{(2)}(\omega_1,\omega_2)$ and $f_{jki}^{(0)}(\omega_1,\omega_2)$.

$$r_{jki}^{(2)}(\omega_1,\omega_2)=\left[\frac{1}{\omega_1\omega_2}+\frac{\exp(-h\beta\omega_1)}{\omega_1(\omega_1-\omega_2)}+\frac{\exp(-h\beta\omega_2)}{\omega_2(\omega_2-\omega_1)}\right] \times g_{jki}(\omega_1,\omega_2), \quad (158)$$

$$f_{jki}^{(0)}(\omega_1,\omega_2)=\frac{h^2}{6}[1+\exp(-h\beta\omega_1)+\exp(-h\beta\omega_2)] \times g_{jki}(\omega_1,\omega_2), \quad (159)$$

in terms of which Eqs. (159) and (155) can be rewritten

$$N_{jki}^{(2)}(\omega_1,\omega_2)=r_{jki}^{(2)}(\omega_1,\omega_2)+r_{jki}^{(2)*}(-\omega_1,-\omega_2), \quad (160)$$

$$\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)=f_{jki}^{(0)}(\omega_1,\omega_2)+f_{jki}^{(0)*}(-\omega_1,-\omega_2). \quad (161)$$

Comparison of Eqs. (158) and (159) shows that $r_{jki}^{(2)}(\omega_1,\omega_2)$ and $f_{jki}^{(0)}(\omega_1,\omega_2)$, which characterize the second-order step-driven response and the equilibrium fluctuations, respectively, in the sense of Eqs. (160) and (161), are related according to

$$r_{jki}^{(2)}(\omega_1,\omega_2)=\frac{1}{E^{(2)}(\omega_1,\omega_2;\beta)}f_{jki}^{(0)}(\omega_1,\omega_2) \quad (162)$$

where

$$E^{(2)}(\omega_1,\omega_2;\beta) =\frac{h^2}{6}\frac{1+\exp(-h\beta\omega_1)+\exp(-h\beta\omega_2)}{\dfrac{1}{\omega_1\omega_2}+\dfrac{\exp(-h\beta\omega_1)}{\omega_1(\omega_1-\omega_2)}+\dfrac{\exp(-h\beta\omega_2)}{\omega_2(\omega_2-\omega_1)}} \underset{\beta\rightarrow 0}{\rightarrow}\frac{1}{\beta^2}. \quad (163)$$

Equation (162) strongly suggests itself as a direct extension to second-order processes of the fluctuation-dissipation theorem of Eq. (58), which relates the Fourier transform $L_{ij}^{(1)}(\omega)$ of the first-order aftereffect function $\phi_{ij}^{(1)}(t)$ to the Fourier transform $G_{ij}^{(0)}(\omega)$ of the equilibrium second fluctuation moment. The universal function $E^{(2)}(\omega_1,\omega_2;\beta)$ is the second-order analog of $E^{(1)}(\omega;\beta)$. It is uniquely quantum-mechanical in origin, corresponding to a slight smearing out of the microscopic contributions to the macroscopic response at extremely high frequencies. In the classical limit, $E^{(2)}(\omega_1,\omega_2;\beta)\rightarrow(1/\beta^2)$ as indicated.

Whereas Eq. (58) constitutes a true thermodynamic relationship, however, Eq. (162) does not. That is, the function $f_{jki}^{(0)}(\omega_1,\omega_2)$ is not macroscopically observable, although its sum with $f_{jki}^{*(0)}(-\omega_1,-\omega_2)$ is, as indicated by Eq. (161).

The specific way in which quantum-mechanical effects enter the picture is evident by first considering what happens in the classical limit. For this case, Eqs. (151), (155), and (157) reduce to

$$N_{jki}^{(2)}(\omega_1,\omega_2)=\frac{h^2\beta^2}{6}[g_{jki}(\omega_1,\omega_2)+g_{jki}^*(-\omega_1,-\omega_2)] =\beta^2\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)=\beta^2 G_{jki}^{(0)}(\omega_1,\omega_2). \quad (164)$$

The functions $\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)$ and $G_{jki}^{(0)}(\omega_1,\omega_2)$ have become equivalent, and measurement of either completely determines $N_{jki}^{(2)}(\omega_1,\omega_2)$. The temporal form of Eq. (164) is obtained immediately from Eqs. (150), (154), and (156).

$$\Phi_{jki}^{(2)}(t)\underset{\beta\rightarrow 0}{\rightarrow}\beta^2\langle q_j q_k q_i(t)\rangle^{(0)}. \quad (165)$$

Substitution of this result into Eq. (145) for $\langle Q_i(t)\rangle^{(2)}$ yields the classical result given previously in Eq. (38).

We decompose $g_{jki}(\omega_1,\omega_2)$ into its real and imaginary, even and odd parts with respect to simultaneous reversal of ω_1 and ω_2.

$$g_{jki}(\omega_1,\omega_2) =\mathrm{Re}^{(+)}g_{jki}(\omega_1,\omega_2)+i\,\mathrm{Im}^{(+)}g_{jki}(\omega_1,\omega_2) +\mathrm{Re}^{(-)}g_{jki}(\omega_1,\omega_2)+i\,\mathrm{Im}^{(-)}g_{jki}(\omega_1,\omega_2). \quad (166)$$

The superscripts (+) and (−) denote the even and

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

odd part, respectively, under the transformation $\omega_1 \rightarrow -\omega_1$, $\omega_2 \rightarrow -\omega_2$. Using this decomposition, the classical relationship (164) becomes

$$N_{jki}^{(2)}(\omega_1,\omega_2)=\frac{\hbar^2\beta^2}{3}[\mathrm{Re}^{(+)}g_{jki}(\omega_1,\omega_2) + i\,\mathrm{Im}^{(-)}g_{jki}(\omega_1,\omega_2)]=\beta^2\bar{G}_{jki}^{(0)}(\omega_1,\omega_2). \quad (167)$$

Thus, in the classical limit we are concerned only with $\mathrm{Re}^{(+)}g_{jki}(\omega_1,\omega_2)$ and $\mathrm{Im}^{(-1)}g_{jki}(\omega_1,\omega_2)$, both of which are determined by experimental knowledge of the complex quantity $\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)=G_{jki}^{(0)}(\omega_1,\omega_2)$.

In the general quantum case, however, $N_{jki}^{(2)}(\omega_1,\omega_2)$ depends upon all four components of $q_{jki}(\omega_1,\omega_2)$ because of the uniquely quantum-mechanical spreading introduced by the quantities

$$\left[\frac{1}{\omega_1\omega_2}+\frac{\exp(\pm\hbar\beta\omega_1)}{\omega_1(\omega_1-\omega_2)}+\frac{\exp(\pm\hbar\beta\omega_2)}{\omega_2(\omega_2-\omega_1)}\right]$$

appearing in Eq. (151). For this case $\bar{G}_{jki}^{(0)}(\omega_1,\omega_2)$ and $G_{jki}^{(0)}(\omega_1,\omega_2)$ are no longer equivalent, and Eq. (155) and (157) constitute two independent complex expressions which can be solved for the four components of $g_{jki}(\omega_1,\omega_2)$. Because of the quantum-mechanical interference among the components of $g_{jki}(\omega_1,\omega_2)$, measurement of both equilibrium third moments $\bar{\Psi}_{jki}^{(0)}(t_1,t_2)$ and $\Psi_{jki}^{(0)}(t_1,t_2)$ is necessary to determine completely the function $N_{jki}^{(2)}(\omega_1,\omega_2)$ and, consequently, by Eq. (150), the second-order step-driven response, $\Phi_{jki}^{(2)}(t)$.

It may be presumed that an analogous quantum-mechanical analysis of the third- and higher-order terms in the step-driven response can be made, although we do not attempt to carry out this laborious program here. Instead we simply refer to the classical relation between the step-driven response and the equilibrium fluctuations, given previously in Eqs. (36) through (39).

14. STEP-DRIVEN NOISE

For step-driven processes, the perturbation expansion of the driven noise $\langle\frac{1}{2}[Q_i(t),Q_j(t+\tau)]_+\rangle$ simplifies considerably, exhibiting a strong formal similarity to the step-driven response $\langle Q_i(t)\rangle$. We can, therefore, use the techniques employed previously for analyzing the step-driven response to discuss the relationship between the step-driven noise and the equilibrium fluctuations.

Consider Eq. (117) for the first-order driven noise $\langle\frac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)}$. For step-function forces, the unsymmetrized term vanishes, and Eq. (117) reduces, upon integration, to

$$\langle\tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)} = -\sum_k F_k\int_{-\infty}^{\infty} dt_1\Gamma(t_1)\langle\tfrac{1}{4}[Q_k^{(0)}(t_1), \times[Q_i^{(0)}(t), Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}. \quad (168)$$

Equation (168) can also be obtained from Eq. (88) for the first-order step-driven response $\langle Q_i(t)\rangle^{(1)}$ by replacing the operator Q_j by the anticommutator $\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+$. Equation (168) relates the first-order step-driven noise $\langle\frac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(1)}$ to the third equilibrium correlation moment

$$\langle\tfrac{1}{4}[Q_k^{(0)}(t_1), [Q_i^{(0)}(t), Q_j^{(0)}(t+\tau)]_+]_+\rangle^{(0)}.$$

In the classical limit it reduces to

$$\langle q_i(t)q_j(t+\tau)\rangle^{(1)}=-\beta\sum_k F_k\langle q_kq_i(t)q_j(t+\tau)\rangle^{(0)}. \quad (169)$$

The formal similarity between Eqs. (88) and (168) also carries over into the higher-order terms. Thus, in the case of step-function forces, Eq. (21) for $\langle\frac{1}{2}[Q_i(t,) Q_j(t+\tau)]_+\rangle^{(2)}$ reduces to

$$\langle\tfrac{1}{2}[Q_i(t), Q_j(t+\tau)]_+\rangle^{(2)} = \left(-\frac{1}{i\hbar}\right)^2\sum_{kl}F_kF_l\int_{-\infty}^{0}dt_1\int_{-\infty}^{t_1}dt_2\langle[Q_l^{(0)}(t_2), \times[Q_k^{(0)}(t_1), \tfrac{1}{2}[Q_i^{(0)}(t), Q_j^{(0)}(t+\tau)]_+]_-]_-\rangle^{(0)} \quad (170)$$

which also follows from Eq. (24) for the second-order step-driven response $\langle Q_i(t)\rangle^{(2)}$, if we replace Q_i by $\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+$. Consequently, the analysis of the previous section for the second-order step-driven response can be applied directly to the second-order step-driven noise. Similarly, it may be assumed that the third- and higher-order terms can also be treated on an equivalent basis.

The consequences of the above formal resemblance can be most simply demonstrated in the classical limit. Consider Eq. (36) for the full step-driven response $\langle q_i(t)\rangle$. Replacing the operator Q_i by the anticommutator $\frac{1}{2}[Q_i,Q_j^{(0)}(\tau)]_+$, which corresponds to replacing the classical variable q_i by the product $q_iq_j(\tau)$, Eq. (36) becomes

$$\langle q_i(t)q_j(t+\tau)\rangle=\langle\exp(-\beta\sum_k F_kq_k)q_i(t)q_j(t+\tau)\rangle^{(0)}/\langle\exp(-\beta\sum_k F_kq_k)\rangle^{(0)}, \quad (171)$$

Equation (171) expresses the step-driven noise $\langle q_i(t)q_j(t+\tau)\rangle$ wholly in terms of the third correlation moment $\langle\exp(-\beta\sum_k F_kq_k)q_i(t)q_j(t+\tau)\rangle^{(0)}$ of the spontaneous equilibrium fluctuations.

It is possible to summarize the results of this section and the preceding one in the following intuitively appealing way. We first differentiate Eq. (36) for $\langle q_i(t)\rangle$ with respect to F_j, evaluating the result at F_1, F_2, $\cdots=0$.

$$\frac{\partial}{\partial F_j}\langle q_i(t)\rangle=-\beta\langle q_jq_i(t)\rangle^{(0)} \quad (172)$$

which is equivalent to Eq. (37).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Taking the second derivative of $\langle q_i(t)\rangle$ with respect to F_j and F_k, we obtain

$$\frac{\partial^2}{\partial F_j \partial F_k}\langle q_i(t)\rangle = \beta^2\langle q_j q_k q_i(t)\rangle^{(0)} \tag{173}$$

which is equivalent to Eq. (38).

On the other hand, differentiating Eq. (171) for $\langle q_j(t)q_i(t+\tau)\rangle$ with respect to F_k, we obtain

$$\frac{\partial}{\partial F_k}\langle q_j(t)q_i(t+\tau)\rangle = -\beta\langle q_k q_j(t)q_i(t+\tau)\rangle^{(0)} \tag{174}$$

which is equivalent to Eq. (169). Letting $t=0$ and replacing τ by t, this becomes

$$\frac{\partial}{\partial F_k}\langle q_j q_i(t)\rangle = -\beta\langle q_k q_j q_i(t)\rangle^{(0)}. \tag{175}$$

Equations (173) and (175) can be combined in the form

$$\frac{\partial^2}{\partial F_j \partial F_k}\langle q_i(t)\rangle = -\beta\frac{\partial}{\partial F_k}\langle q_j q_i(t)\rangle = \beta^2\langle q_j q_k q_i(t)\rangle^{(0)} \tag{176}$$

which constitutes a triple relationship among the second-order response, the first-order noise, and the equilibrium third moment for a step-driven process. It is apparent that further differentiation of Eqs. (36) and (171) would yield a whole hierarchy of analogous higher order thermodynamic relationships.

Although they apply literally only to step-driven process, Eqs. (172) and (176) exhibit most of the essential elements of the more general theory. Therefore, the results presented above characterize the general structure of irreversible thermodynamics.

Finally, we compare our results for a step-driven process with the results of time-independent equilibrium fluctuation theory. Letting $t=0$, Eqs. (172) and (176) reduce to

$$\frac{\partial}{\partial F_j}\langle q_i\rangle^{(0)} = -\beta\langle q_i q_j\rangle^{(0)}, \tag{177}$$

$$\frac{\partial^2}{\partial F_j \partial F_k}\langle q_i\rangle^{(0)} = \beta^2\langle q_i q_j q_k\rangle^{(0)} = -\beta\frac{\partial}{\partial F_k}\langle q_i q_j\rangle^{(0)}. \tag{178}$$

Equations (177) and (178) are precisely those which can be derived for a generalized canonical ensemble using standard equilibrium fluctuation theory.[16]

15. THE PATH DISTRIBUTION FUNCTION

Recently one of us has discussed the first-order term in the nonequilibrium path distribution function $W_1(q,t)$[8]. This function specifies the probability that the macroscopic variable corresponding to the operator Q has the value q in the driven ensemble at the time t. In this section we review the theory of the path distribution function and its application to the first-order problem discussed in Secs. 5 through 7. We also discuss the path distribution function for a step-driven process.

In order to keep the notation simple, we restrict ourselves initially to a one-dimensional process. The distribution function $W_1(q,t)$ can be expressed in terms of its characteristic function $K_1(\nu,t)$.

$$W_1(q,t) = \frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty} d\nu e^{i\nu q}K_1(\nu,t) \tag{179}$$

whence $K_1(\nu,t)$ is given by

$$K_1(\nu,t) = \frac{1}{(2\pi)^{\frac{1}{2}}}\int_{-\infty}^{\infty} dq e^{-i\nu q}W_1(q,t)$$

$$= \frac{1}{(2\pi)^{\frac{1}{2}}}\langle e^{-i\nu q(t)}\rangle = \frac{1}{(2\pi)^{\frac{1}{2}}}\,\mathrm{Tr}\,\rho^{(0)}e^{-i\nu Q(t)}, \tag{180}$$

where $e^{-i\nu Q(t)} = U^\dagger(t)e^{-i\nu Q}U(t)$. Then

$$W_1(q,t) = \mathrm{Tr}\,\rho^{(0)}\delta(q-Q(t)) = \langle\delta(q-Q(t))\rangle, \tag{181}$$

where $\delta(q-Q(t))$ is the driven δ-function operator $U^\dagger(t)\delta(q-Q)U(t)$, which selects from $\rho^{(0)}$ the appropriate contributions to $W_1(q,t)$.

Since $W_1(q,t)$ is just the expectation of value of $\delta(q-Q)$ in the driven system at time t, the theory developed previously for the driven response $\langle Q(t)\rangle$ can be applied directly to the path distribution function. Thus, for example, the first-order term $W_1^{(1)}(q,t)$ is obtained in symmetrized form from Eq. (88) for $\langle Q_i(t)\rangle^{(1)}$ by simply replacing Q_i by $\delta(q-Q)$.

$$W_1^{(1)}(q,t) = -\int_{-\infty}^{t} dt_1 F(t_1)\int_{-\infty}^{\infty} dt_1'\Gamma(t_1-t_1')$$

$$\times\langle\tfrac{1}{2}[\dot{Q}^{(0)}(t_1'-t),\delta(q-Q)]_+\rangle^{(0)}, \tag{182}$$

the t dependence in the integrand has been transferred to $\dot{Q}$ by performing a unitary transformation with $\exp\{\pm i[H^{(0)}t/\hbar]$.

The quantity $\langle\frac{1}{2}[\dot{Q}^{(0)}(t_1'-t),\delta(q-Q)]_+\rangle^{(0)}$ is interpreted in the following way. Since the classical analog of the operator $\delta(q-Q)$ is simply the δ function $\delta(q-q')$, we can calculate the equilibrium correlation moment of the variables corresponding to the operators $\dot{Q}^{(0)}(t_1'-t)$ and $\delta(q-Q)$ according to

$$\langle\tfrac{1}{2}[\dot{Q}^{(0)}(t_1'-t),\delta(q-Q)]_+\rangle^{(0)}$$

$$= \int_{-\infty}^{\infty} dq'\delta(q-q')W_1^{(0)}(q')\langle\dot{Q}^{(0)}(t_1'-t)\rangle_{q'}^{(0)} \tag{183}$$

where $W_1^{(0)}(q)$ is the equilibrium probability distribu-

[16] See for example R. F. Greene and H. B. Callen, Phys. Rev. 83, 1231 (1951).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

tion, and $\langle\dot{Q}^{(0)}(t_1'-t)\rangle_q^{(0)}$ denotes the equilibrium expectation value of the variable corresponding to the operator $\dot{Q}$ at time $(t'-t)$ conditional on the variable corresponding to Q having the value q at time zero. The q' integration can be performed immediately to yield

$$\langle\tfrac{1}{2}[\dot{Q}^{(0)}(t_1'-t),\delta(q-Q)]_+\rangle^{(0)} = W_1^{(0)}(q)\langle\dot{Q}^{(0)}(t_1'-t)\rangle_q^{(0)}. \quad (184)$$

Substituting the result (184) back into Eq. (182) we obtain

$$W_1^{(1)}(q,t) = -W_1^{(0)}(q)\int_{-\infty}^{t} dt_1 F(t_1) \times\int_{-\infty}^{\infty} dt_1'\Gamma(t_1-t_1')\langle\dot{Q}^{(0)}(t_1'-t)\rangle_q^{(0)}. \quad (185)$$

The corresponding first-order term $W_1^{(1)}(q_1,\cdots,q_n;t)$ in the path distribution function for an n-dimensional process can be developed in a completely analogous way. In place of the single operator $\delta(q-Q)$, we introduce a symmetrized form of the product $\delta(q_1-Q_1)\cdots\delta(q_n-Q_n)$ of δ-function operators. The result is

$$W_1^{(1)}(q_1,\cdots,q_n;t) = -W_1^{(0)}(q_1,\cdots,q_n)\sum_{j=1}^{n}\int_{-\infty}^{t} dt_1 F_j(t_1) \times\int_{-\infty}^{\infty} dt_1'\Gamma(t_1-t_1')\langle\dot{Q}_j^{(0)}(t_1'-t)\rangle_{q_1\cdots q_n}^{(0)}. \quad (186)$$

$W_1^{(0)}(q_1,\cdots,q_n)$ is the simultaneous equilibrium probability distribution for the variables $q_1,\cdots,q_n$, while $\langle\dot{Q}_j^{(0)}(t_1'-t)\rangle^{(0)}{}_{q_1\cdots q_n}$ denotes the equilibrium expectation value of the variable corresponding to $\dot{Q}_j$ at time $(t_1'-t)$ conditional on the variables corresponding to $Q_i,\cdots,Q_n$ having the values $q_1,\cdots,q_n$ at time zero. In the classical limit, Eq. (186) reduces to

$$W_1^{(1)}(q_1,\cdots,q_n;t) \underset{\beta\to 0}{\longrightarrow} -\beta W_1^{(0)}(q_1,\cdots,q_n) \times\sum_{j=1}^{n}\int_{-\infty}^{t} dt_1 F_j(t_1)\langle\dot{q}_j(t_1-t)\rangle_{q_1\cdots q_n}^{(0)}. \quad (187)$$

Equation (186) constitutes a generalized statement of the fluctuation-dissipation theorem, expressing $W_1^{(1)}(q_1,\cdots,q_n;t)$ in terms of the equilibrium probability distribution $W_1^{(0)}(q_1,\cdots,q_n)$ and the equilibrium conditional expectation value $\langle\dot{Q}_j^{(0)}(t_1'-t)\rangle_{q_1\cdots q_n}^{(0)}$. Since all of the previous theorems regarding the first-order problem can be derived from Eq. (186), this form can be considered the fundamental relationship for the linear theory of irreversibility.

We now consider the full path distribution function $W_1(q_1,\cdots,q_n;t)$ for a classical step-driven process. The step-driven response is written in terms of $W_1(q_1,\cdots,q_n;t)$ as

$$\langle q_i(t)\rangle = \int_{-\infty}^{\infty} dq_1\cdots\int_{-\infty}^{\infty} dq_n q_i W_1(q_1,\cdots,q_n;t). \quad (188)$$

According to Eq. (36), however, $\langle q_i(t)\rangle$ can also be written

$$\langle q_i(t)\rangle = \int_{-\infty}^{\infty} dq_1\cdots\int_{-\infty}^{\infty} dq_n q_i W_1^{(0)}(q_1,\cdots,q_n) \times\langle\exp[-\beta\sum_j F_j q_j(-t)\rangle_{q_1\cdots q_n}^{(0)}/ \langle\exp(-\beta\sum_j F_j q_j)\rangle^{(0)}. \quad (189)$$

The t dependence of the time-stationary quantity $\langle\exp(-\beta\sum_j F_j q_j)q_i(t)\rangle^{(0)}$ has been translated into the exponential $\exp(-\beta\sum_j F_j q_j)$.

$$\langle\exp[-\beta\textstyle\sum_j F_j q_j(-t)]\rangle_{q_1\cdots q_n}^{(0)}$$

denotes the equilibrium expectation value of

$$\exp(-\beta\textstyle\sum_j F_j q_j)$$

at time $-t$ conditional on all variables having the values $q_1,\cdots,q_n$ at time zero.

Since Eqs. (188) and (189) must be identical, it follows that the step-driven path distribution function $W_1(q_1,\cdots,q_n;t)$ is given, in the classical limit, by

$$W_1(q_1,\cdots,q_n;t) = W_1^{(0)}(q_1,\cdots,q_n)\langle\exp[-\beta\sum_j F_j q_j(-t)]\rangle_{q_1\cdots q_n}^{(0)}/ \langle\exp-\beta\sum_j F_j q_j)\rangle^{(0)}. \quad (190)$$

Equation (190) expresses the path distribution function, characterizing the time evolution of a step-driven ensemble, in terms of the equilibrium probability distribution $W_1^{(0)}(q_1,\cdots,q_n)$, together with the conditional expectation value $\langle\exp[-\beta\sum_j F_j q_j(-t)\rangle_{q_1\cdots q_n}^{(0)}$.

The significance of this result for the path distribution function can be made more apparent by rewriting Eq. (36) for $\langle q_i(t)\rangle$ in the form

$$\langle q_i(t)\rangle = \int_{-\infty}^{\infty} dq_1\cdots\int_{-\infty}^{\infty} dq_n W_1^{(0)}(q_1,\cdots,q_n) \times\exp(-\beta\sum_j F_j q_j)\langle q_i(t)\rangle_{q_1\cdots q_n}^{(0)}/ \langle\exp(-\beta\sum_j F_j q_j)\rangle^{(0)}. \quad (191)$$

However, letting $t=0$ in Eq. (189), we find that the initial perturbed equilibrium probability distribution

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$W_1(q_1,\cdots,q_n;0)$ is given by

$$W_1(q_1,\cdots q_n;0) = W_1^{(0)}(q_1;\cdots,q_n)\exp(-\beta\sum_j F_j q_j)/ \times\langle\exp(-\beta\sum_j F_j q_j)\rangle^{(0)}. \quad (192)$$

Inserting this result in Eq. (191), we obtain

$$\langle q_i(t)\rangle = \int_{-\infty}^{\infty} dq_1\cdots\int_{-\infty}^{\infty} dq_n W_1(q_1,\cdots,q_n;0) \times\langle q_i(t)\rangle_{q_1\cdots q_n}{}^{(0)}. \quad (193)$$

Equation (193) shows explicitly how the step-driven response $\langle q_i(t)\rangle$ is built up from the regression of the equilibrium fluctuations, characterized by the equilibrium conditional expectation value $\langle q_i(t)\rangle_{q_1\cdots q_n}{}^{(0)}$, and weighted according to the initial perturbed distribution $W_1(q_1,\cdots,q_n;0)$. Although this result is precisely that which we might intuitively expect, it has often been pointed out in the literature[2,6] that there is no clear *a priori* justification for identifying the behavior of a system undergoing an irreversible process with the spontaneous equilibrium fluctuations in this way. The equilibrium fluctuations are microscopic in nature and generally on an extremely small scale, whereas the macroscopic response functions measured in the laboratory are normally orders of magnitude larger. Nevertheless, the proof of the assumption that macroscopic processes follow the same laws of regression as the equilibrium fluctuations is provided by Eq. (193).

16. THE JOINT PATH DISTRIBUTION FUNCTION

Just as a more detailed description of the equilibrium behavior can be obtained by introducing joint probability distributions containing two or more times, it is possible to describe in greater detail the evolution of a driven ensemble by introducing joint path distribution functions. In this final section we extend the theory of the previous section to include the joint path distribution $W_2(q,t;q',t')$, which specifies the probability that the variable corresponding to the operator Q has the value q at time t *and* the value q' at time t' in a driven ensemble. We consider explicitly the case of a single variable, although the extension of the theory to multidimensional processes is quite straightforward.

$W_2(q,t;q',t')$ can be expressed in terms of its characteristic function $K_2(\nu,t;\nu',t')$.

$$W_2(q,t;q',t') = \frac{1}{2\pi}\int_{-\infty}^{\infty} d\nu\int_{-\infty}^{\infty} d\nu' e^{i\nu q}e^{i\nu' q'}K_2(\nu,t;\nu',t') \quad (194)$$

where $K_2(\nu,t;\nu',t')$ is given by

$$K_2(\nu,t;\nu',t') = \frac{1}{2\pi}\int_{-\infty}^{\infty} dq\int_{-\infty}^{\infty} dq' e^{-i\nu q}e^{-i\nu' q'}W_2(q,t;q',t') = \frac{1}{2\pi}\langle e^{-i\nu Q(t)}e^{-i\nu' Q(t')}\rangle. \quad (195)$$

According to the discussion of Sec. 3, the quantum-mechanical form of the driven second moment $K_2(\nu,t;\nu',t')$ is

$$K_2(\nu,t;\nu',t') = \frac{1}{2\pi}\langle\tfrac{1}{2}[e^{-i\nu Q(t)},e^{-i\nu' Q(t')}]_+\rangle^{(0)} \quad (196)$$

so that Eq. (194) for $W_2(q,t;q',t')$ becomes

$$W_2(q,t;q',t') = \frac{1}{(2\pi)^2}\int_{-\infty}^{\infty} d\nu\int_{-\infty}^{\infty} d\nu'\langle\tfrac{1}{2}[e^{i\nu[q-Q(t)]},e^{i\nu'[q'-Q(t')]}]_+\rangle^{(0)} = \langle\tfrac{1}{2}[\delta(q-Q(t)),\delta(q'-Q(t'))]_+\rangle^{(0)}. \quad (197)$$

Equation (197) states that $W_2(q,t;q',t')$ is just the driven correlation moment between the δ-function operators $\delta(q-Q(t))$ and $\delta(q'-Q(t'))$. Therefore, the treatment of driven second moments developed throughout the preceding sections of this paper is immediately applicable to the joint path distribution function.

We limit ourselves here to a discussion of the joint path distribution function for a classical step-driven process. The driven second moment $\langle q(t)q(t')\rangle$ can be written in terms of $W_2(q,t;q',t')$ as

$$\langle q(t)q(t')\rangle = \int_{-\infty}^{\infty} dq\int_{-\infty}^{\infty} dq' qq' W_2(q,t;q',t'). \quad (198)$$

On the other hand, according to Eq. (171), $\langle q(t)q(t')\rangle$ can be computed according to

$$\langle q(t)q(t')\rangle = \int_{-\infty}^{\infty} dq\int_{-\infty}^{\infty} dq' qq' W_2^{(0)}(q;q',t-t') \times\frac{\langle e^{-\beta F q(-t')}\rangle_{q,q'(t-t')}{}^{(0)}}{\langle e^{-\beta F q}\rangle^{(0)}} \quad (199)$$

where $W_2^{(0)}(q;q',t-t')$ is the (time-stationary) equilibrium joint probability distribution and $\langle e^{-\beta F q(-t')}\rangle_{q,q'(t-t')}{}^{(0)}$ denotes the equilibrium expectation value of $e^{-\beta F q}$ at time $-t'$ conditional on q at time zero and q' at time $(t-t')$.

From Eqs. (198) and (199) it follows that the step-driven joint path distribution function is given in the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

classical limit, by

$$W_2(q,t;q',t')=W_2^{(0)}(q;q',t-t')\times\frac{\langle e^{-\beta Fq(-t')}\rangle_{q,q'(t-t')}^{(0)}}{\langle e^{-\beta Fq}\rangle^{(0)}}. \quad (200)$$

Thus, $W_2(q,t;q',t')$ is related in a particularly simple way to the equilibrium joint probability $W_2^{(0)}(q;q',t-t')$ and the equilibrium conditional expectation value $\langle e^{-\beta Fq(-t')}\rangle_{q,q'(t-t')}^{(0)}$.

Finally, we rewrite Eq. (171) for $\langle q(t)q(t')\rangle$ so as to further emphasize the relationship of this quantity to the regression of equilibrium fluctuations.

$$\langle q(t)q(t')\rangle=\int_{-\infty}^{\infty}dqW_1^{(0)}(q)e^{-\beta Fq}\frac{\langle q(t)q(t')\rangle_q^{(0)}}{\langle e^{-\beta Fq}\rangle^{(0)}}. \quad (201)$$

$\langle q(t)q(t')\rangle_q^{(0)}$ denotes the second equilibrium correlation moment between $q(t)$ and $q(t')$, conditional on the value q at time zero. However, according to Eq. (192) $W_1^{(0)}(q)e^{-\beta Fq}/\langle e^{-\beta Fq}\rangle^{(0)}$ is just the initial ($t=0$) perturbed equilibrium distribution function $W_1(q,0)$. Hence, Eq. (200) becomes

$$\langle q(t)q(t')\rangle=\int_{-\infty}^{\infty}dqW_1(q,0)\langle q(t)q(t')\rangle_q^{(0)}. \quad (202)$$

This result shows explicitly how the step-driven second moment $\langle q(t)q(t')\rangle$ is built up from the regression of the equilibrium fluctuations, characterized by the conditional equilibrium second moment $\langle q(t)q(t')\rangle_q^{(0)}$ and weighted according to the initial perturbed distribution $W_1(q,0)$.

APPENDIX A

In this appendix we compare a system driven from $t\to-\infty$ by the step-function forces defined in Sec. 4 to the subsequent motion of a system characterized at $t=0$ by the generalized canonical density operator $\rho(0)$ of Eq. (25).

Consider the first-order term $\langle Q_i(t)\rangle^{(1)}$ in the response during a step-driven process, as given by Eq. (23). The equilibrium expectation value appearing in this expression can be written

$$\begin{aligned}&\langle[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-\rangle^{(0)}\\&=\langle Q_j^{(0)}(t_1)Q_i^{(0)}(t)-Q_i^{(0)}(t)\exp[\pm\beta H^{(0)}]Q_j^{(0)}(t_1)\rangle^{(0)}\\&=\langle Q_j^{(0)}(t_1)Q_i^{(0)}(t)-\exp[\beta H^{(0)}]Q_j^{(0)}(t_1)\\&\qquad\times\exp[-\beta H^{(0)}]Q_i^{(0)}(t)\rangle^{(0)}\end{aligned} \quad (A\text{-}1)$$

where we have inserted $\exp[\pm\beta H^{(0)}]$ in the second term as indicated and permuted the operators cyclicly.

This form can be further rewritten as follows.

$$\begin{aligned}&\langle[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-\rangle^{(0)}\\&=-\int_0^\beta d\lambda_1\frac{\partial}{\partial\lambda_1}\langle\exp[\lambda_1H^{(0)}]Q_j^{(0)}(t_1)\\&\qquad\times\exp[-\lambda H^{(0)}]Q_i^{(0)}(t)\rangle^{(0)}\\&=-\int_0^\beta d\lambda_1\langle[H^{(0)},Q_j^{(0)}(t_1-i\hbar\lambda_1)]_-Q_i^{(0)}(t)\rangle^{(0)}.\end{aligned} \quad (A\text{-}2)$$

Noting that $[H^{(0)},Q_j^{(0)}(t_1-i\hbar\lambda_1)]=-i\hbar\dot{Q}_j^{(0)}(t_1-i\hbar\lambda_1)$, we have

$$\begin{aligned}&\langle[Q_j^{(0)}(t_1),Q_i^{(0)}(t)]_-\rangle^{(0)}\\&\qquad=i\hbar\int_0^\beta d\lambda_1\langle\dot{Q}_j^{(0)}(t_1-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}.\end{aligned} \quad (A\text{-}3)$$

Inserting the result (A-3) into Eq. (23) and performing the time integration, we obtain

$$\begin{aligned}\langle Q_i(t)\rangle^{(1)}=-\sum_jF_j\int_0^\beta d\lambda_1[&\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}\\&-\lim_{t_1\to-\infty}\langle Q_j^{(0)}(t_1-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}].\end{aligned} \quad (A\text{-}4)$$

The contribution to (A-4) from the $t_1\to-\infty$ limit is evaluated by taking

$$\begin{aligned}&\lim_{t_1\to-\infty}\int_0^\beta d\lambda_1\langle Q_j^{(0)}(t_1-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}\\&=\lim_{T\to-\infty}\frac{1}{T}\int_0^\beta d\lambda_1\int_0^T dt_1\langle Q_j^{(0)}(t_1-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}.\end{aligned} \quad (A\text{-}5)$$

Because of the factor $1/T$, the oscillatory part of the integrand gives no contribution, and we are left with

$$\begin{aligned}&\lim_{t_1\to-\infty}\int_0^\beta d\lambda_1\langle Q_j^{(0)}(t_1-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}\\&\qquad=\int_0^\beta d\lambda_1\langle\tilde{Q}_i\tilde{Q}_j\rangle^{(0)}=\beta\langle\tilde{Q}_i\tilde{Q}_j\rangle^{(0)}\end{aligned} \quad (A\text{-}6)$$

where $\tilde{Q}_1$ denotes the diagonal portion of the operator Q_i with respect to the unperturbed Hamiltonian $H^{(0)}$.

Using the result (A-6), Eq. (A-4) for $\langle Q_i(t)\rangle^{(1)}$ becomes

$$\begin{aligned}\langle Q_i(t)\rangle^{(1)}=-\sum_jF_j\Big[&\int_0^\beta d\lambda_1\langle Q_j^{(0)}(-i\hbar\lambda_1)Q_i^{(0)}(t)\rangle^{(0)}\\&-\beta\langle\tilde{Q}_i\tilde{Q}_j\rangle^{(0)}\Big].\end{aligned} \quad (A\text{-}7)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The paradoxical contrast between Eq. (A-7) and Eq. (32) for $\langle Q_i(t)\rangle^{(1)}$ has been discussed by R. Kubo,[9] who suggests that the former equation refers to an adiabatic system, whereas the latter refers to an isothermal system, so that the two need not be equal.

However, the same difficulty is found to arise even in an equilibrium isothermal system. Thus, in the limit $t\rightarrow\infty$, the equilibrium correlation moment

$$\langle \tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}$$

becomes

$$\lim_{t\rightarrow\infty}\langle \tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}=\langle \tilde{Q}_i\tilde{Q}_j\rangle^{(0)} \qquad \text{(A-8)}$$

where the limit is evaluated as in Eq. (A-6). In order for the ensemble to be ergodic, however, in the sense that as $t\rightarrow\infty$ the quantities involved become completely uncorrelated, we require

$$\lim_{t\rightarrow\infty}\langle \tfrac{1}{2}[Q_i,Q_j^{(0)}(t)]_+\rangle^{(0)}=\langle Q_i\rangle^{(0)}\langle Q_j\rangle^{(0)}. \qquad \text{(A-9)}$$

We believe that the resolution of this problem lies in the following interpretation. Throughout the discussion we consider an ensemble in continual interaction with a temperature reservoir. This should be contrasted with the interpretation adopted by Kubo, which is that the interaction with the temperature reservoir is removed at the moment of imposition of the applied forces, the ensemble thereafter being adiabatic. In our interpretation the Hamiltonian $H^{(0)}$ therefore contains a term corresponding to the interaction with a temperature reservoir, which we have not indicated explicitly for reasons to be explained momentarily. The additional interaction term induces incoherent transitions among the states of the system such that the ensemble "forgets" the details of its previous behavior after a sufficiently long time. This insures that the ensemble satisfies the ergodic requirement states in Eq. (A-9).

The justification for not indicating the interaction term explicitly in calculating the driven response is as follows. It is always possible to choose the term of interaction with the temperature reservoir to be so small that, for times comparable to those in which we are interested, the disordering effects arising from this source are negligible. Since Eq. (32) gives the first-order response $\langle Q_i(t)\rangle^{(1)}$ corresponding to an ensemble chosen so as to be in (generalized) canonical equilibrium up to $t=0$, it must therefore yield the appropriate evolution of $\langle Q_i(t)\rangle^{(1)}$ for any finite time $t>0$.

However, in the limit $t\rightarrow\infty$, the effects of the continued temperature interaction manifest themselves, regardless of the strength of the interaction. In this limit Eq. (32) reduces to

$$\langle Q_i(t)\rangle^{(1)}\underset{t\rightarrow\infty}{\rightarrow}-\sum_j F_j[\beta\langle \tilde{Q}_i\tilde{Q}_j\rangle^{(0)}-\beta\langle Q_i\rangle^{(0)}\langle Q_j\rangle^{(0)}]. \qquad \text{(A-10)}$$

Here it is necessary to take explicit account of the interaction with the temperature reservoir. This can be accomplished, according to a comparison of Eqs. (A-8) and (A-9), by replacing the quantity $\tilde{Q}_i$ by the average value $\langle Q_i\rangle^{(0)}$. The foregoing arguments apply as well to the time evolution of the full step-driven response $\langle Q_i(t)\rangle$ given in Eq. (26), in the expansion of which Eq. (32) is the first-order term.

In order to make Eq. (A-7) consistent with our interpretation, we recall that the quantity $\tilde{Q}_i$ appearing in it arose from the evaluation of a $t\rightarrow\infty$ limit. Again we take explicit account of the temperature interaction in this limit by replacing $\tilde{Q}_i$ by $\langle Q_i\rangle^{(0)}$. Thus, Eq. (A-7) becomes identical to Eq. (32). If we evaluate Eq. (24), for $\langle Q_i(t)\rangle^{(2)}$ and the corresponding higher-order terms in the response $\langle Q_i(t)\rangle$ during a step-driven process, replacing quantities of the type $\tilde{Q}_i$ by $\langle Q_i\rangle^{(0)}$ whenever they appear, we obtain expressions identical to Eqs. (33), (34), etc. The technique for accomplishing this is essentially an iteration of that employed in putting Eq. (23) into the form (A-7).

APPENDIX B

The causal nature of a linear process finds expression in the well-known Kramers-Krönig dispersion formulas relating the real and imaginary parts of the complex admittance matrix elements.

We first indicate the proof of these relations. Consider the Fourier transform of Eq. (63) for $Y_{ij}(\omega)$.

$$\int_{-\infty}^{\infty}d\omega e^{i\omega t}\frac{Y_{ij}(\omega)}{i\omega}=\int_{-\infty}^{\infty}d\omega\int_0^{\infty}dt'e^{i\omega(t-t')}\phi_{ij}^{(1)}(t')$$

$$=2\pi\int_0^{\infty}dt'\delta(t-t')\phi_{ij}^{(1)}(t'). \qquad \text{(B-1)}$$

Therefore,

$$\int_{-\infty}^{\infty}d\omega e^{i\omega t}\frac{Y_{ij}(\omega)}{i\omega}=\begin{cases}2\pi\phi_{ij}^{(1)}(t) & \text{for } t>0\\ 0 & \text{for } t<0\end{cases} \qquad \text{(B-2)}$$

whence it follows that $Y_{ij}(\omega)/i\omega$ can have poles only in the upper half of the complex ω plane.

For a function $Y_{ij}(\omega)/i\omega$ which is everywhere analytic in the lower half of the ω plane, Cauchy's integral theorem states that

$$\frac{Y_{ij}(\omega)}{i\omega}=\frac{P}{i\pi}\oint d\omega'\frac{Y_{ij}(\omega')}{i\omega'(\omega'-\omega)}$$

$$=-\frac{P}{i\pi}\int_{-\infty}^{\infty}d\omega'\frac{Y_{ij}(\omega')}{i\omega'(\omega'-\omega)} \qquad \text{(B-3)}$$

where the complex integration is taken around the contour shown in Fig. 5, and P denotes a Cauchy principal value. Decomposing $Y_{ij}(\omega)$ into its real and imaginary parts $Y_{ij}(\omega)=\mathrm{Re}\,Y_{ij}(\omega)+i\,\mathrm{Im}\,Y_{ij}(\omega)$ and equating the real and imaginary parts of Eq. (B-3), we

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

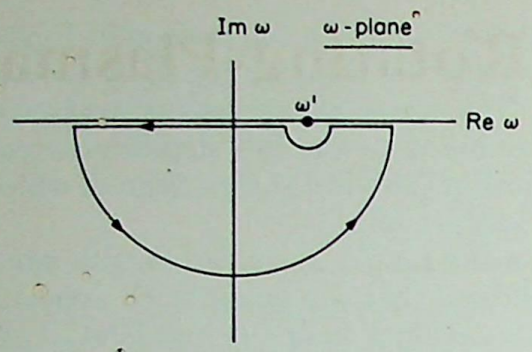

FIG. 5.

obtain

$$\frac{\text{Re } Y_{ij}(\omega)}{\omega}=-\frac{P}{\pi}\int_{-\infty}^{\infty}d\omega'\frac{\text{Im } Y_{ij}(\omega')}{\omega'(\omega'-\omega)}, \tag{B-4}$$

$$\frac{\text{Im } Y_{ij}(\omega)}{\omega}=\frac{P}{\pi}\int_{-\infty}^{\infty}d\omega'\frac{\text{Re } Y_{ij}(\omega')}{\omega'(\omega'-\omega)}. \tag{B-5}$$

Equations (B-4) and (B-5) are the Kramers-Krönig dispersion relations.

We use Eq. (B-5), together with the results of equilibrium fluctuation theory, to derive the $t=0$ form of the fluctuation-dissipation theorem, Eq. (73). Letting $\omega=0$, the quantity $[\text{Im } Y_{ij}(\omega)/\omega]$ becomes simply the capacitance $[\partial\langle q_j\rangle^{(0)}/\partial F_i]$, so that Eq. (B-5) assumes the form

$$\frac{\partial\langle q_j\rangle^{(0)}}{\partial F_i}=\frac{P}{\pi}\int_{-\infty}^{\infty}d\omega'\frac{\text{Re } Y_{ij}(\omega')}{\omega'^2}. \tag{B-6}$$

However, for a generalized canonical ensemble in contact with a series of reservoirs with constant intensive parameters $\cdots, F_i, F_j, \cdots$, the equilibrium second moment $\langle q_iq_j\rangle^{(0)}$ is given by[16]

$$\langle q_iq_j\rangle^{(0)}=-\frac{1}{\beta}\frac{\partial\langle q_j\rangle^{(0)}}{\partial F_i}. \tag{B-7}$$

Substitution of Eq. (B-7) into Eq. (B-6) yields the result

$$\langle q_iq_j\rangle^{(0)}=-\frac{P}{\pi\beta}\int_{-\infty}^{\infty}d\omega\frac{\text{Re } Y_{ij}(\omega)}{\omega^2} \tag{B-8}$$

which is identical to Eq. (73) with t set$=0$.

APPENDIX C

In this Appendix, following Kubo,[9] we evaluate the universal function $\Gamma(t)$, defined in Eq. (83). For $t>0$, this can be calculated by performing a contour integration around the upper half of the complex ω plane, while for $t<0$, the integration is taken around the lower half-plane. We consider explicitly the case $t>0$, since the $t<0$ calculation proceeds in an identical way.

Letting $\alpha=\hbar\beta\omega$, Eq. (83) can be rewritten as a contour integral in the complex α plane.

$$\Gamma(t)=\frac{1}{\pi\hbar}\oint d\alpha\exp\left(\frac{\alpha t}{i\hbar\beta}\right)\frac{1}{\alpha}\left(\frac{1-e^{-\alpha}}{1+e^{-\alpha}}\right). \tag{C-1}$$

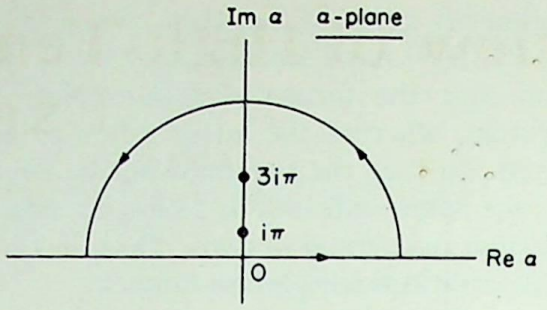

FIG. 6.

The integral is to be taken along the contour shown in Fig. 6. The integrand has simple poles at $\alpha_l=(2l+1)i\pi$, $l=0, \pm1, \cdots$. The residue of the integrand at the pole is obtained by letting $\alpha=\alpha_l+\Delta\alpha$, multiplying the integrand by $\Delta\alpha$, and taking the limit as $\Delta\alpha\to0$. Thus

residue at α_l

$$=\lim_{\Delta\alpha\to0}\frac{\Delta\alpha}{\pi\hbar}\exp\left[i\frac{(\alpha_l+\Delta\alpha)}{\hbar\beta}t\right]\frac{1}{(\alpha_l+\Delta\alpha)}\left[\frac{1-e^{-(\alpha_l+\Delta\alpha)}}{1+e^{-(\alpha_l+\Delta\alpha)}}\right]$$

$$=\frac{2}{\pi\hbar}\frac{\exp[-(2l+1)\pi t/\hbar\beta]}{(2l+1)\pi i}\lim_{\Delta\alpha\to0}\frac{\Delta\alpha}{(1-e^{-\Delta\alpha})}$$

$$=\frac{2\exp[-(2l+1)\pi t/\hbar\beta]}{\pi^2\hbar(2l+1)i}. \tag{C-2}$$

Equation (C-1) ls now evaluated by taking

$$\Gamma(t)=2\pi i\sum_{l=0}^{\infty}(\text{residue at }\alpha_l)$$

$$=\frac{4}{\pi\hbar}\sum_{l=0}^{\infty}\frac{\exp[-(2l+1)\pi t/\hbar\beta]}{(2l+1)}. \tag{C-3}$$

It is convenient to take the time derivative of Eq. (C-3) before performing the summation.

$$\frac{d\Gamma(t)}{dt}=-\frac{4}{\hbar^2\beta}\sum_{l=0}^{\infty}\exp[-(2l+1)\pi t/\hbar\beta]$$

$$=-\frac{4}{\hbar^2\beta}\frac{\exp[-(\pi t/\hbar\beta)]}{1-\exp(-2\pi t/\hbar\beta)}=-\frac{2}{\hbar^2\beta}\,\text{csch}\frac{\pi t}{\hbar\beta}. \tag{C-4}$$

In performing the summation in Eq. (C-4) we have made use of the expansion $\sum_l x^l=[1/(1-x)]$. We now integrate Eq. (C-4) with respect to t, which yields finally the desired result,

$$\Gamma(t)=\frac{2}{\pi\hbar}\ln\coth\frac{\pi t}{2\hbar\beta}. \tag{C-5}$$

The corresponding result for $t<0$ is identical to Eq. (C-5), except that t is replaced by $-t$. Thus, for all t, we can write that

$$\Gamma(t)=\frac{2}{\pi\hbar}\ln\coth\frac{\pi|t|}{2\hbar\beta}. \tag{C-6}$$

Review of High-Temperature Rotating-Plasma Experiments

JOHN M. WILCOX

Lawrence Radiation Laboratory, University of California, Berkeley, California

THE major experimental effort in the controlled thermonuclear reaction program has been based upon three different methods of plasma confinement—the pinch approach, the stellarator approach, and the magnetic-mirror approach.[1] Among the other approaches being investigated is the rotating-plasma system. By means of crossed electric and magnetic fields in a geometry having cylindrical symmetry, a charged particle can be induced to rotate about the axis of symmetry. The new degree of freedom associated with this rotation may offer new possibilities for containing and heating plasmas. Early work in this field was done at Oak Ridge.[2] We discuss here four experimental approaches that are being actively investigated: the Berkeley Homopolar device,[3] the Los Alamos Ixion,[4] and the Berkeley[5] and Moscow[6] ion-magnetron experiments.

BASIC CONCEPTS

We first discuss a few concepts which are important in these experiments, and then describe the four experiments individually. We will examine the electric drift velocity with the resulting diamagnetic current, the dielectric constant of a rotating plasma, the magnetic-mirror enhancement with a rotating plasma, and finally the possible formation of anode sheaths.

The well-known "electric drift velocity"[7] is imparted to a charged particle in the presence of crossed electric and magnetic fields. For a singly charged particle we have

$$\mathbf{V}_E = c(\mathbf{E}\times\mathbf{B})/B^2, \tag{1}$$

or

$$V_E = 10^8 E/B, \tag{2}$$

where the electric drift velocity V_E is in cm/sec, the electric field E is in volts/cm, and the magnetic field B is in gauss. Thus, for example, in an electric field of 3 kv/cm and a magnetic field of 10 kilogauss, a deuteron will have a velocity of 3×10^7 cm/sec and thus an energy of 1 kv. The electric drift velocity is perpendicular to both the electric and magnetic fields. It does not depend on the mass of the particle, and it is in the same direction for positive and negative particles. Thus, in an infinite plane geometry, ions and electrons have the same velocity and direction and there is no net electric current flow. However, in these experiments the presence of a radial electric field causes the particles to move with a radius of curvature R, and a centrifugal force term must be considered, so that the balance of forces on a particle is now

$$e[\mathbf{E}+(1/c)\mathbf{V}_D\times\mathbf{B}]+mV_D^2\mathbf{R}/R^2=0, \tag{3}$$

where $\mathbf{R}$ is the radius vector of the particle position, m is the mass of the particle, e is the algebraic value of its charge, and c is the velocity of light. This leads to a drift velocity

$$\mathbf{V}_D = c\frac{\mathbf{E}\times\mathbf{B}}{B^2} - \frac{mcV_D^2}{e}\frac{\mathbf{B}\times\mathbf{R}}{B^2R^2}. \tag{4}$$

Ions and electrons now move with different velocities, and an electric current $\mathbf{j}_\theta$ flows. Since the $\mathbf{j}_\theta\times\mathbf{B}$ force of the magnetic field is opposing the centrifugal force of the rotating particles, the plasma "leans" on the magnetic lines, and if the plasma rotational energy is sufficient the magnetic lines bow outward, thus weakening the field near the axis. The diamagnetic drift current density is

$$\mathbf{j}_\theta = (Ne/c)(\mathbf{V}_d - \mathbf{V}_e), \tag{5}$$

where N is the particle density (electrostatic forces will insure approximate equality of ion and electron densities), $\mathbf{V}_d$ is obtained from Eq. (3) applied to ions, and $\mathbf{V}_e$ is obtained from Eq. (3) applied to electrons. Since the centrifugal force on the electrons is small compared with the centrifugal force on the ions, we have

$$\mathbf{j}_\theta \simeq -(NMV_d^2)[(\mathbf{B}\times\mathbf{R})/B^2R^2], \tag{6}$$

where M is the mass of the ions. Since $\mathbf{B}\times\mathbf{R}$ is in the

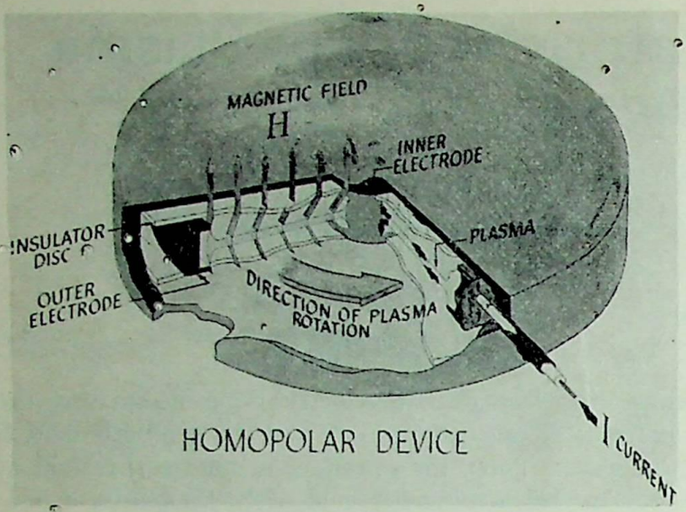

FIG. 1. Diagram of Homopolar device.

same direction as the external solenoidal current that gives rise to **B**, $\mathbf{j}_0$ is a diamagnetic current. For the case mentioned in the foregoing with an outward electric field of 3 kv/cm and a magnetic field of 10 kilogauss, and with a deuteron density of $10^{14}/\text{cm}^3$ and a radius of curvature of 10 cm, the drift-current density is 34 amp/cm^2.

A plasma that is rotating in equilibrium with an applied electric field E can be compared with a condenser that is in equilibrium with an applied electric field; however, in the rotating plasma the energy is stored in the form of kinetic energy of the moving particles. We can derive the dielectric constant k of the plasma by equating this kinetic-energy density to the increased energy density of the electric field,

$$\frac{kE^2}{8\pi}=\frac{E^2}{8\pi}+\frac{1}{2}\rho V_E^2=\frac{E^2}{8\pi}\left(1+\frac{4\pi\rho c^2}{B^2}\right), \quad (7)$$

where ρ is the density of the plasma, and where use has been made of Eq. (2), so that the dielectric constant of the rotating plasma is

$$k=1+(4\pi\rho c^2/B^2). \quad (8)$$

This number can be very large in a practical situation; for the case mentioned in the foregoing the dielectric constant is 3.7×10^4. The effect of the displacement of the magnetic lines has not been included in this derivation.

Post has shown that under certain conditions a charged particle is reflected if it moves into a region of increasing magnetic field, so that particles can be contained if the magnetic field is made to increase at both ends.[8] Post has also shown that in order for a particle to pass through the mirror, we must have

$$W_{11}(c)\geq W_\perp(c)[(B_m/B_c)-1], \quad (9)$$

where $W_\perp$ and W_{11} are the perpendicular and parallel kinetic energies, and c refers to the center and m to the mirror. If the plasma is rotating, the centrifugal force tends to keep the particles away from the axis, where they must go to escape, and thus the mirror containment efficiency is enhanced.[3] An elegant theoretical treatment[4] shows that for a rotating plasma the foregoing inequality is to be replaced by

$$W_{11}(c)\geq W_\perp(c)[(B_m/B_c)-1]+\tfrac{1}{2}MV_E^2(c)[1-(B_c/B_m)], \quad (10)$$

where M is the mass of the particle and V_E is given by Eq. (2). In this case $W_\perp$ is to be measured in the rotating frame of reference. Thus a rotating plasma is more efficiently contained by the magnetic mirror.

Finally, we consider the possible formation of an anode sheath for the case in which the anode surface is parallel to the magnetic field lines. In a conventional electron-discharge tube the sheath forms at the cathode because of the high mobility of the electrons. However, for motion perpendicular to a magnetic field the ions have a greater mobility, while the electrons are tightly confined to their field lines. The ions acquire their electric drift energy by moving a short distance in a direction parallel to the electric field. As they move away from the surface of the anode a region with net negative space charge is left behind. In this narrow sheath a large voltage drop may be present. In some of the experiments the presence of the anode sheath is considered desirable, while in others it is avoided.

THE HOMPOLAR EXPERIMENT

In the Homopolar experiment the emphasis has been on the study of the basic properties of rotating plasmas, therefore argon has been used for the most part. In this experiment[3] the object is to create a spinning disk of plasma which is somewhat similar to the flywheel of a conventional Homopolar generator. The experimental geometry is shown in Fig. 1. The vacuum chamber, which has a diameter of 30 cm and a height of 5 cm, is placed between the pole tips of a magnet so that there is an axial magnetic field of up to 18 000 gauss. A radial electric field exists between the inner electrode and the concentric cylindrical outer electrode. By operation at a comparatively high gas pressure ($\sim$100 μ) the anode sheath effects are largely removed, so that the electric

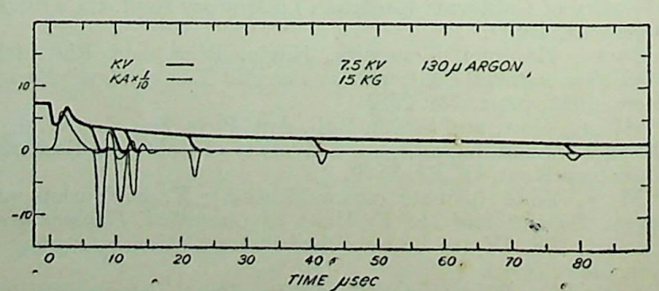

FIG. 2. Current and voltage wave forms in the Homopolar device.

[8] R. F. Post, Bull. Am. Phys. Soc. Ser. II, 3, 196 (1958); *Second International Conference on Peaceful Uses of Atomic Energy, Geneva, 1958*, paper No. 377.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

field exists through the body of the plasma, and the entire plasma is set spinning with the electric drift velocity. Initially a large pulse of current is required to ionize the gas and supply the energy of rotation. Once the plasma has been set in rotation a much smaller current will be drawn, due only to the viscous drag of the plasma. In Fig. 2 the heavy trace shows the behavior of the voltage, while the positive light trace, which extends from 0 to 6 μsec, is the charging-current pulse. The negative current pulses are discussed below.

The equivalent circuit of the Homopolar experiment is shown in Fig. 3. Thus the spinning plasma is represented by a capacitance C_H, which arises from the dielectric effect discussed above, with a parallel resistance R_L, which represents viscous effects. Indeed this geometry may have application as a very-low-inductance capacitor for driving controlled-fusion experiments.[9]

Plasma rotation has been demonstrated by three observations. If we consider the rotating Homopolar as a charged capacitance, then it should be possible to recover the initial charge that was fed in by the pulse of charging current. For this purpose the terminals of the Homopolar are rapidly shorted with the crowbar circuit shown in Fig. 3. The resulting current pulse is in the opposite direction to the charging current, and resembles one of the negative traces shown in Fig. 2. By application of the crowbar at various times, the amount of energy still stored in the system after any interval can be measured. The dissipation of stored energy is indicated by the decreased crowbar current traces at longer times. The crowbar method has shown that under favorable conditions more than half of the input energy can be recovered.

Plasma rotation can also be observed by the Doppler shift of the emitted radiation, as shown in Fig. 4. A spectrometer views the rotating plasma through a tangential port. If the direction of the magnetic field is reversed, then, according to Eq. (1), the direction of rotation will be reversed. The rotational velocities calculated from the Doppler shift agree with the velocities calculated from the crowbar current. Rotational energies of a few hundred electron volts are measured during operation with argon.

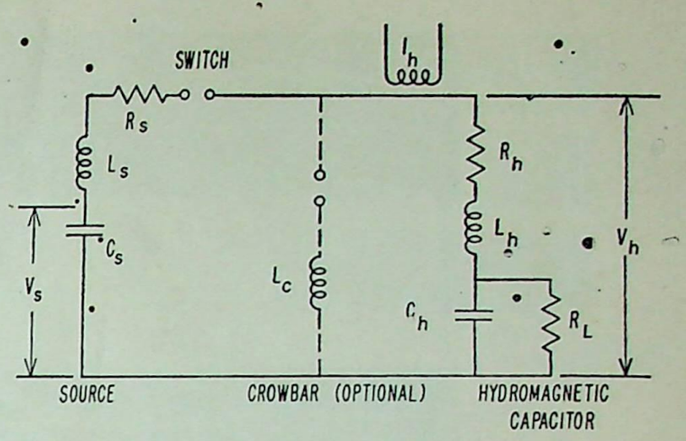

FIG. 3. Equivalent circuit of Homopolar device.

A third observation of plasma rotation is the "spin loop" data. As shown above, the centrifugal force from the plasma rotation gives rise to a diamagnetic current in the θ direction, and thus to a radial component of magnetic field. We may think of the rotating particles as "leaning" on the magnetic lines and bending them outward. This effect is independent of the direction of rotation. Thus the signal in a magnetic probe coil which is oriented to detect H_r should be independent of the sense of rotation. The observed spin-loop signal is shown in Fig. 5, and indeed has the same polarity for both directions of rotation. A slight misalignment of the pickup coil is believed to account for the difference in amplitude between the two signals.

Thus a considerable storage of rotating energy has been demonstrated in the Homopolar experiment in a geometry which is stable for times of the order of 100 μsec. For controlled-fusion applications some of this energy will have to be converted to random or heat energy, which presumably can be accomplished with suitable perturbations in the electric or magnetic fields.

The same basic ideas have been incorporated in the improved geometry shown in Fig. 6. In this case the centrifugal force is more effective in pulling the plasma away from the insulators. Experiments are just beginning with this geometry; however, a decay time of several hundred microseconds has been observed.

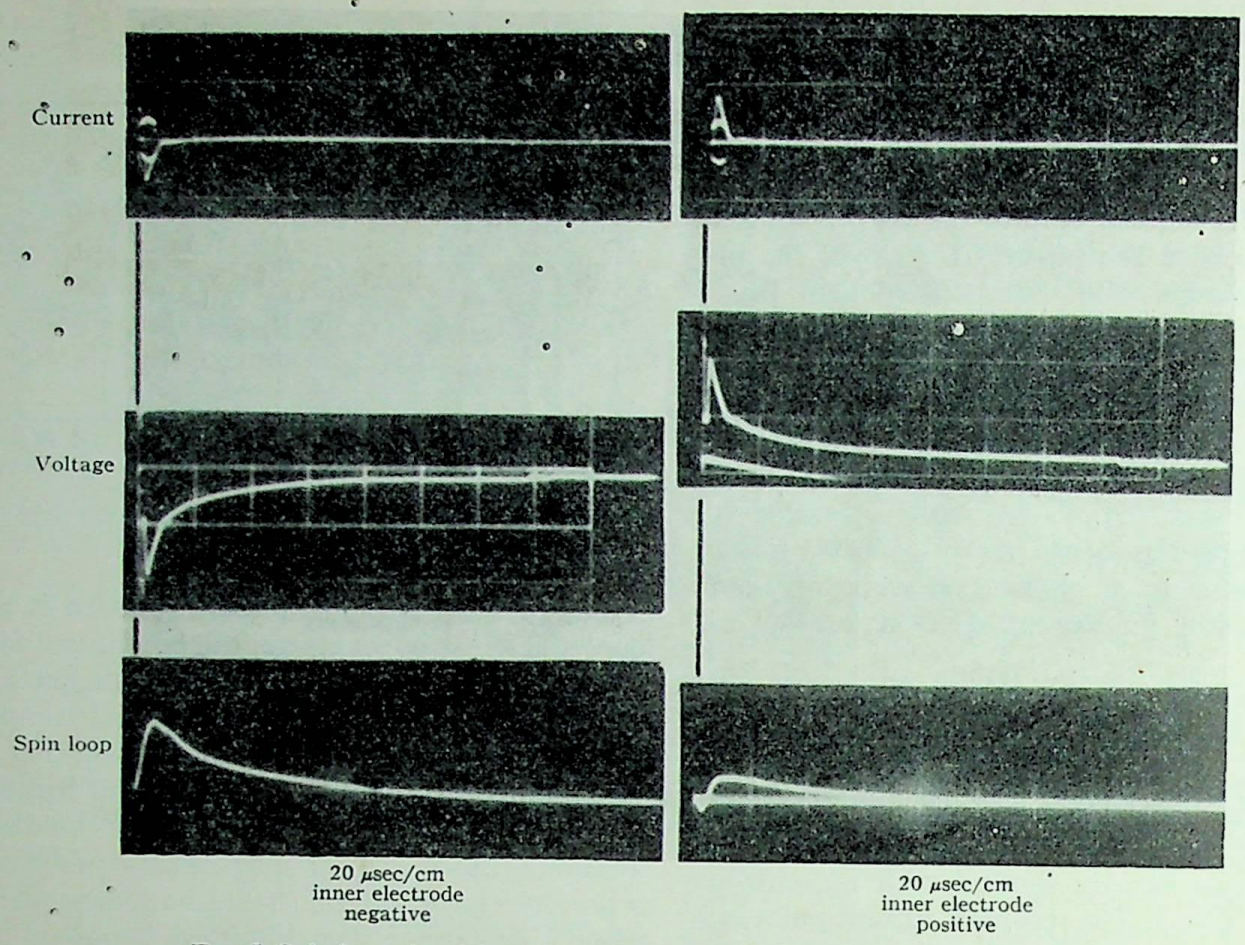

FIG. 5. Spin-loop signal from Homopolar device—100 μ Ar; 17.4 kilogauss; 7 kv.

IXION

This experiment is named for the king in Greek mythology who aspired to the love of a goddess and was therefore sentenced to be forever bound to a flaming rotating wheel.

The Ixion[4] geometry as shown in Fig. 7 is long (86 cm) in comparison with the flat-disk geometry of the Homopolar. The pulsed magnetic field increases from 9 kilogauss at the median plane to 20 kilogauss at the mirror throat, and the pressure between pulses is 2×10^{-6} mm Hg. The first experiments were done with metallic central electrodes, but the latest model has a plasma "center rod." A puff of deuterium gas corresponding to one micron pressure in the apparatus is ionized and driven into the machine by a magnetic shock coil. This plasma electrode makes electrical contact with a pair of tungsten ring electrodes located at the mirror throats. After the plasma electrode has arrived, the high voltage (10 kv) is pulsed on. For about 200 μsec negligible current is drawn, and then a sudden impulse of current of about 20 000 amp is drawn for 25 μsec, as shown in Figs. 8(A) and 8(B), which have a sweep speed of 200 μsec/cm. The voltage falls to about one-half its original value as the discharge occurs, and then decays to zero in about 500 μsec. This current spike and the voltage behavior are interpreted as being caused by the development of a rotating plasma. The subsequent decay of the voltage is attributed to the loss of plasma to the walls.

Plasma rotation has been demonstrated by the crowbar technique and by Doppler-shift observations. When Ixion is short-circuited, about one-fifth of the original charge can be recovered. In the Homopolar experiment one-half the original charge was recovered, but this was

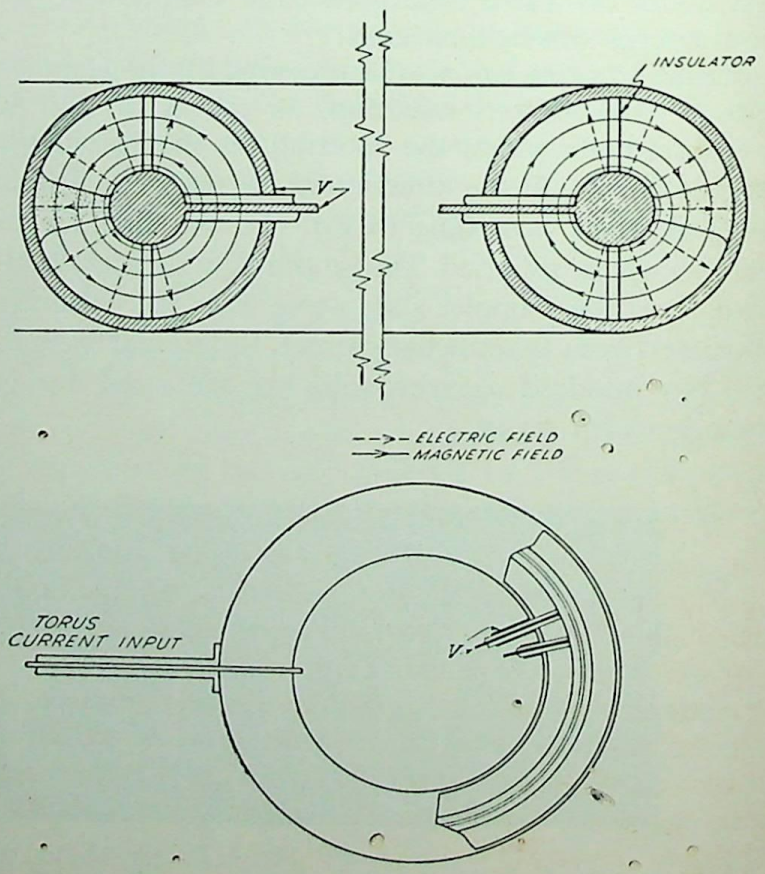

FIG. 6. Later version of Homopolar device.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

with operation with argon, and these machines are found experimentally to operate better with heavy gases than with deuterium. The capacitance of Ixion can be calculated from the plasma dielectric constant [given in Eq. (8)] increased by a factor of the order of 1.5, which corrects for the diamagnetic weakening of the applied magnetic field. Using this capacitance and the observed amount of charge that can be recovered, one can compute that the rotating deuterium plasma would have an equivalent pressure of 5.6 μ. The pressure of the injected deuterium is 1.5 μ; the discrepancy may be accounted for by the presence of impurities or by an error in the geometrical correction.

The Doppler shift that occurs when the magnetic field is reversed is shown in Fig. 8(D), which is a profile of a carbon line. The drift velocity of 4×10^6 cm/sec calculated herefrom is consistent with the value calculated from the applied electric and magnetic fields. The spectral analysis also shows many other impurity lines during the current pulse, and H and D lines lasting for 100 μsec after the current pulse.

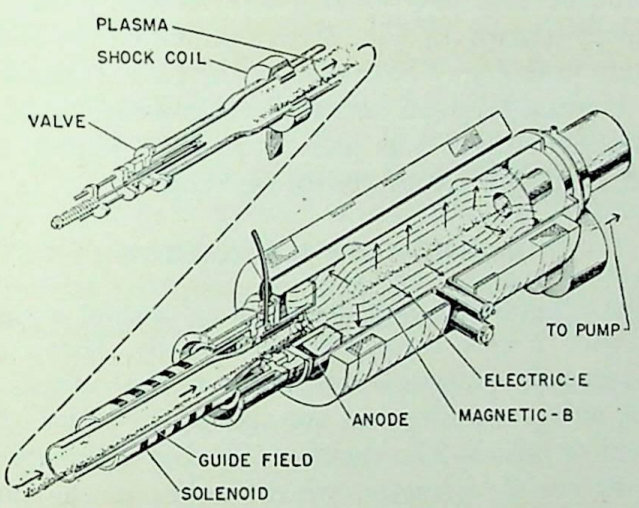

FIG. 7. Diagram of Ixion.

The high-impedance delay for 200 μsec after the voltage is pulsed on was examined with an earlier model having a metallic central electrode. By electrostatic probing it was found that most of the voltage drop occurred just outside the anode, corresponding to the presence of an electron sheath as discussed above. Thus it is seen that the electric field does not penetrate the main body of the plasma and bulk rotation does not occur.

If the magnetic field is lowered, the voltage raised, or the pressure raised excessively, the discharge is oscillatory as shown in Fig. 8(C). The voltage falls to zero almost at once. Neutrons occur during the current spike in this mode of operation, with about 10^5 neutrons per discharge at 40 kv and a detectable yield at 10 kv. If the magnetic field is increased so as to obtain the capacitive-type operation shown in Figs. 8(A) and 8(B), the neutrons disappear. The origin of these neutrons has not been satisfactorily explained.

In an Ixion with a metal center rod, large diamagnetic

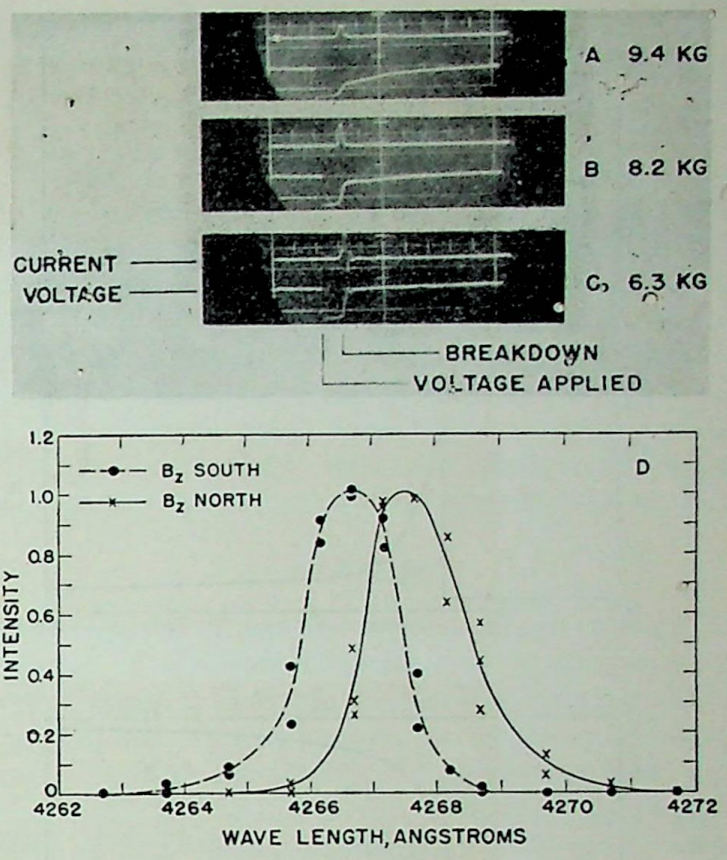

FIG. 8. Experimental data from Ixion.

signals were observed with a magnetic probe coil inside the center rod during the oscillatory discharge of Fig. 8(C). These signals corresponded to almost complete removal of the axial magnetic field from the center of the machine. The diamagnetic effect decreased to zero as the probe was moved away from the center plane to the mirror throat. Diamagnetic signals have also been observed on Ixion with the plasma center rod. The diamagnetic decrease for voltage-holding operation is of the order of 30% at the center, and decreases to zero at the mirror throat.

BERKELEY ION MAGNETRON

This experiment[5] utilizes a long solenoidal magnetic field (120 cm) having a mirror throat at each end and a metal center electrode, as shown in Fig. 9. However, the philosophy on which this is based is quite different from that in the two preceding experiments. The tube is operated at the comparatively low pressure of a

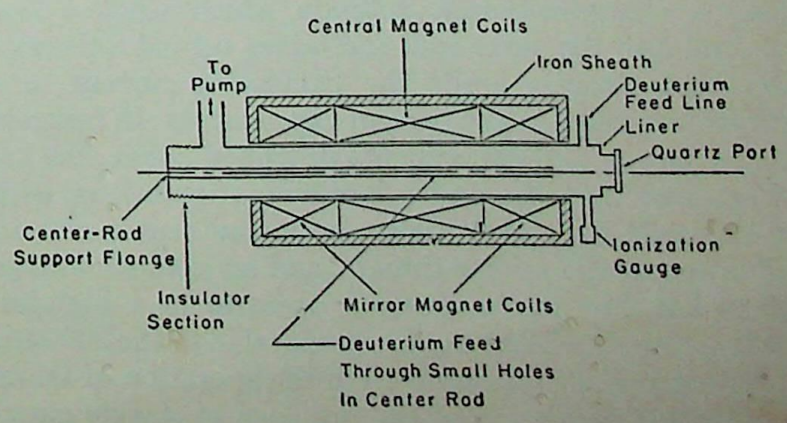

FIG. 9. Diagram of Berkeley ion magnetron.

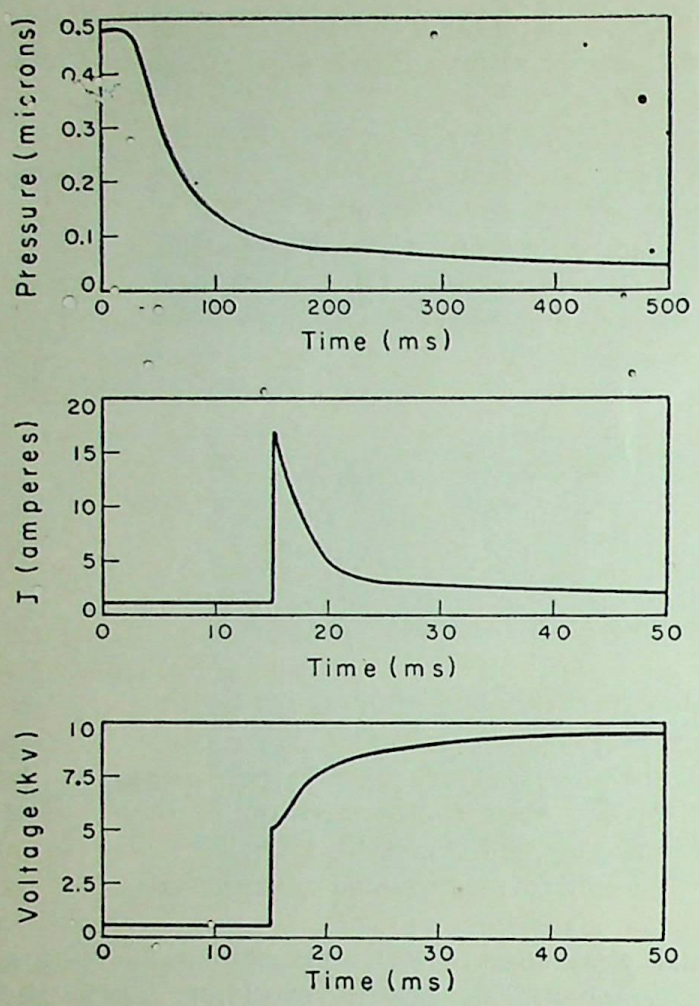

FIG. 10. Experimental data from Berkeley ion magnetron—0.35 μ deuterium; 9 kilogauss; 10 kv.

fraction of a micron, and thus the anode sheath develops about the central electrode. Since this sheath contains a considerable density of ionizing electrons circulating around the axis, a neutral deuterium molecule that enters the sheath volume has a good chance of being ionized. The ion thus formed will be rapidly accelerated out of the sheath by the electric field, and will circulate around the axis in magnetronlike orbits with a kinetic energy equal to the potential energy at the point in the sheath at which it was ionized. The magnetic field is considerably stronger than the magnetron cutoff value, so that the circulating ions cannot reach the outer wall. Each time the ion returns toward the axis it is reflected by the sheath potential; the sheath protects the central electrode. After several revolutions this fast ion undergoes a charge-exchange collision which sends a fast neutral into the outer wall and leaves behind a thermal ion. This process limits the circulating current to a rather low value in the present experiments. In contrast to the two pulsed experiments described above, the ion magnetron operates under continuous conditions, with a magnetic field of 3 kilogauss at the center and 12 kilogauss at the mirror throats, and an applied voltage of 10 kv. The ion magnetron operates in a high-impedance mode which may be comparable to the 200-μsec "waiting period" encountered in the operation of Ixion.

The first indication of the presence of sizable circulating ion currents came with the observation of rather violent oscillations of the center electrode. This electrode was mechanically supported at only one end, so that it was free to oscillate as a pendulum. This motion could be viewed through the quartz port shown in Fig. 9. Several exploratory experiments supported the view that the force responsible for these oscillations came from the recoil of ions accelerated in the sheath. From the magnitude of the forces involved, the circulating current was estimated to be equivalent to about 100 amp when the current drawn by the tube was about 1 amp.

When the tube voltage is turned on, the behavior of the gauge pressure and tube current is as shown in Fig. 10. The size and duration of the initial current pulse can be computed by considering that the neutral gas initially present flows into the sheath with thermal velocity.

With steady operation at a tube voltage of 10 kv and a tube current of 1 amp, neutrons are produced at a rate of a few times 10^4 per sec. They are probably produced by head-on collisions between ions entering the sheath and ions leaving the sheath. When the geometry shown in Fig. 9 was modified to include vacuum pumping at both ends of the tube, the neutron rate increased by an order of magnitude, since the circulating current was able to reach a higher value before being limited by charge exchange.

MOSCOW ION MAGNETRON

This experiment[6] also utilizes a solenoidal magnetic field with mirror throats on both ends. However, a direct-current plasma beam serves as the central electrode, which is positive at voltages up to 40 kv, direct current or pulsed. The vacuum chamber is 170 cm long and 50 cm in diameter, which makes it the largest among the experiments discussed here. The system geometry shown in Fig. 11 has been drawn from a sketch made by Dr. M. S. Yoffe. The central magnetic field is 8 kilogauss, rising to 12 kilogauss at the mirror throats. Oil diffusion pumps at the ends and evaporated-titanium pumps in the middle give a large vacuum-pumping rate and a base pressure of 10^{-7} mm Hg.

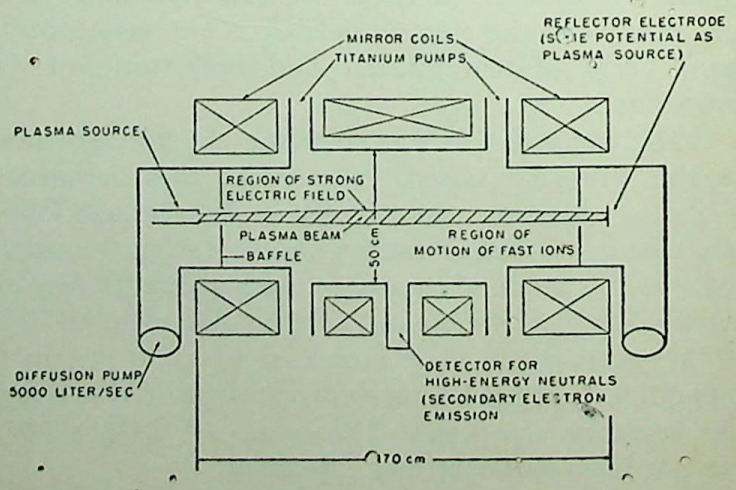

FIG. 11. Diagram of Moscow ion magnetron (Yoffe).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

High-energy neutrals from the charge-exchange process previously mentioned are detected by secondary-electron emission, as shown in Fig. 11. Neutron production is observed with a plastic phosphor viewed by a phototube. In one type of experiment the high voltage is pulsed on with a square wave for from 10 μsec to 2 msec. At the end of the square wave the voltage is returned to ground in about 10^{-7} sec. The high-energy neutral-detector response decreases approximately exponentially with a lifetime of 1 or 2 msec, and neutron pulses are seen for a few msec after the voltage has gone to zero. Thus the decay time of the system appears to be 1 or 2 msec, somewhat longer than has been observed with the Homopolar or Ixion; however, the system dimensions are larger in this experiment, and the mode of operation is considerably different.

This ion magnetron makes 10^7 to 10^8 neutrons per second at 40 kv, with a tube current of 1 or 2 amp. The curve for neutron yield *vs* voltage follows the general shape of the D^+ cross section.

In an earlier smaller model, extensive measurements were made with hot and cold probes of the radial distribution of potential. Three modes of operation may be distinguished. If the applied voltage is very high, all the ions supplied by the plasma source are accelerated radially as soon as they leave the mouth of the plasma source, so that there is no central beam. As the applied voltage is reduced, a second mode of operation is reached in which the central beam reaches a considerable distance into the machine, but not all the way across. In this case a stable radial potential distribution is observed, and most of the electric field is concentrated in the vicinity of the axis, corresponding to the formation of the anode sheath discussed above. Finally, if the applied voltage is decreased still more, a mode of operation is attained in which the central plasma column reaches across the entire length of the machine. In this regime the radial potential distribution oscillates at frequencies of 200 to 400 kc between a steep distribution which corresponds to the presence of an anode sheath and a sloping distribution which corresponds to the absence of a sheath voltage drop. It is not known at present whether these oscillations can be avoided. Since a plasma central electrode offers many advantages, the question of its stability is an important one.

SUMMARY

By emphasis of various aspects of the fundamental concepts of electric drift velocity, diamagnetic azimuthal current, dielectric constant of rotating plasma, magnetic mirror enhancement, and anode sheath formation, the four experimental approaches have been developed. It is clear that this work has only begun to define the problems and possibilities of rotating plasmas. We hope that this article has pointed out some of the challenging experimental and theoretical problems that remain to be solved.

I. INTRODUCTION

STUDY of ultrasonic absorption due to chemical relaxation in electrolytes has recently had considerable development.† As a result of the comprehensive work done by Professor Tamm and his associates at the University of Göttingen and Professor Leonard and his associates at the University of California in Los Angeles, this aspect of sound absorption is understood somewhat better compared to the thermal or structural relaxation in fluids. Recently Litovitz and his associates have contributed much to the understanding of the basic mechanisms responsible for the sound absorption in chemical solutions.

Einstein[1] was the first to point out that chemical processes can account for sound absorption in partially dissociated gases. He made a theoretical estimate of its contribution in nitrogen tetroxide.[2] According to him, the excess sound absorption in partially dissociated gases such as nitrogen tetroxide is due to dissociation.

Liebermann[3] in 1949 considered sound absorption in a chemically active fluid. According to him, chemically active media may exhibit unusual physical properties such as dynamic compressibility whose value depends upon the compression rate in contrast to the conventional static value. The case is similar for dynamic specific heat, which depends upon the rate of change of temperature. These distinctions between static and dynamic values become prominent when high-frequency sound waves pass through the medium which is in chemical equilibrium, provided the equilibrium is pressure and temperature dependent. Such chemical reactions occurring in liquids are expected to affect the propagation of sound waves too.

Acetic acid is the first liquid in which the chemical process was found to be responsible for excess sound absorption. Spakowski[4] and Richards[2] suggested that the absorption of ultrasonic waves arises from the perturbation of the equilibrium between the dimer and monomer forms of acetic acid. Pinkerton[5] in 1948 confirmed experimentally the existence of the relaxation phenomenon in acetic acid and, with Lamb,[6] studied the absorption and dispersion of ultrasonic waves in acetic acid in great detail. They showed that a dispersion and maximum in the value of absorption per wavelength occur and that a relaxation process which arises from the perturbation of the chemical equilibrium due to passage of sound waves does exist. Recent measurements of Piercy and Lamb[7] at low concentrations of acetic acid indicate the presence of a second relaxation region with a characteristic frequency an order of magnitude higher than that for the pure acid. This second relaxation is ascribed to the monomer-dimer reaction, whereas the first relaxation in pure acid is still unexplained. Litovitz and Carnevale[8] have studied effects of pressure on ultrasonic relaxation in pure acid and their results, however, are in agreement with monomer-dimer theory.

* Part of this work was carried out while the author was at Ultrasonics Research Laboratory, Western Reserve University, Cleveland, Ohio.

Another indication of the existence of such perturbation effects of sound waves on chemical equilibrium resulting in sound absorption is provided by measurements of the ultrasonic absorption in sea water and its comparison with fresh water below one megacycle per second by several workers.[9–14] Leonard discovered that the cause of excess sound absorption in sea water is the presence of $MgSO_4$. Above 1 Mc the absorption is similar to that of fresh water. Below 1 Mc the value of α/ν^2, where α is the absorption coefficient and ν the frequency, is found to increase with decrease in frequency. The absorption coefficient is governed by an empirical relation of the type

$$2\alpha = A_1[K\omega^2/(\omega^2+K^2)]+A_2\omega^2,$$

where ω is the angular frequency and K's and A's are constants. The first term has the form characteristic of a relaxation phenomenon, and this led to the suggestion that chemical relaxation is the process responsible for the excess sound absorption. Wilson[15] later reported that the relaxation frequency does exist near 130 kc. According to Liebermann,[3] the relaxation term arises from a pressure-dependent equilibrium of a chemical reaction within the liquid, and the cause of the excess sound absorption in $MgSO_4$ solutions lies in the dissociation reaction $AB \rightleftarrows A+B$ involving magnesium-sulfate molecules or ions. He developed a theory of sound propagation in chemically active media, but its application to $MgSO_4$ suffered from some errors with regard to concentration dependence; for example, he suggested that the absorption is proportional to the square root of the concentration. Wilson and Tamm and Kurtze[16a] have shown independently that absorption is linearly proportional to concentration. This led to the explanation that the process is unimolecular, $A \rightleftarrows B$, with a relaxing transition between two energy states of the ion pairs. Barthel[17] later discussed the concentration behavior and concluded that if the activity coefficients for ionic reactants are taken into consideration the experimental results of Wilson which suggest unimolecular reaction will fit equally well with the dissociation reaction. Bies[18] also considered the dependence of the activities of the ions with the passage of sound waves. He studied the effect of the dielectric constant of the solvent on the absorption and concluded in favor of a dissociation mechanism as responsible for the excess sound absorption.

Tamm and Kurtze[19] assume the existence of the complex MeR, H_2O, where Me = metal and R = radical. For this complex two different possibilities of dissociation are assumed in order to explain the presence of two relaxation frequencies. The other possibilities which may cause the anomalous sound absorption, according to Tamm, are ion association or a complicated combination of molecular dissociation and hydrolysis. Thermal relaxation is ruled out, simply because there is no appreciable change in the absorption near 4°C where isothermal propagation is expected to take place. The assumption of ion association, i.e., the association of anion and cation to form an ion pair (ion pair $\rightleftarrows$ anion and cation) gives a similar dependence of absorption and relaxation on frequency as in the case of the dissociation process. But this assumption explains only one relaxation mechanism. It does not explain the second increase in the product of absorption cross section and wavelength, which is observed in the case of 2–2-valent electrolytes.

Litovitz and Smithson[20] suggest that all observed data can be explained on the basis of the assumption that the reaction is between two dipole molecules. They rule out the reaction between two ions of unlike sign as the rate-determining step in the primary relaxation process. Their results also indicate that the hydrogen ion is not involved in the rate-determining reaction causing the observed relaxational effects.

II. THEORY

(a) Excess Sound Absorption

A plane acoustic wave in an absorbing medium can be represented in the form

$$\xi_x = \xi_0 \exp[i\omega(t-x/V_0)-\alpha x], \qquad (1)$$

where ξ_x is the amplitude at a distance x and α is the amplitude absorption coefficient. This expression can be written in the form

$$\xi_x = \xi_0 \exp[i\omega(t-x/V)], \qquad (2)$$

where

$$1/V = (1/V_0)-(i\alpha/\omega). \qquad (3)$$

If it is assumed that the chemical equilibrium is pressure dependent, then a change in the pressure will cause a shift in the equilibrium. Such a medium has a complex compressibility. The isothermal compressibility of a solution may be assumed to be equal to the isothermal compressibility of the solvent (assumed real) plus a complex factor due to the perturbed chemical equilibrium. Thus

$$\beta = \beta_0+\beta'. \qquad (4)$$

The contribution to the intensity attenuation coefficient per wavelength of the complex compressibility is given by

$$2\alpha\lambda = -2\pi \operatorname{Im}(\beta'/\beta_0). \tag{5}$$

Consider the case of a two-state equilibrium reaction

$$A \underset{k_2}{\overset{k_1}{\rightleftarrows}} B.$$

If N represents the molal fraction in the excited state, then at equilibrium

$$dN/dt = k_1 - (k_1+k_2)N = 0. \tag{6}$$

Similarly in the case of a dissociation reaction

$$AB \underset{k_2}{\overset{k_1}{\rightleftarrows}} A+B$$

at equilibrium,

$$dN/dt = k_1(1-N) - k_2N^2. \tag{7}$$

If the equilibrium of the reaction is perturbed only slightly by the change of acoustic pressure, the rate of return towards equilibrium is, to a first-order approximation,

$$d(\Delta N)/dt = K(\Delta N - \Delta N_0), \tag{8}$$

where ΔN_0 represents the magnitude of small perturbation and K is defined as the equilibrium reaction rate. In the case where ΔN_0 is a constant the solution is given by

$$\Delta N = \Delta N_0[1-\exp(-Kt)], \tag{9}$$

where $1/K$ is called the time constant or relaxation time τ of the reaction in the vicinity of equilibrium. However, if the perturbing force is the acoustic wave, the perturbation varies periodically with time, for example, as $\exp i\omega t$, then the solution is given by

$$\Delta N = \Delta N_0/(1+i\omega/K). \tag{10}$$

Liebermann[3] showed that the dynamic partial isothermal compressibility β' is given by

$$\beta' = \beta_0'/(1+i\omega/K), \tag{11}$$

where β_0' is the portion of the static isothermal compressibility which arises from the supposed chemical reaction.

Neglecting the small specific heat term, the contribution to the sound absorption coefficient arising from the chemical reaction is given by

$$2\alpha = \frac{\beta_0'}{\beta_0} \frac{\omega^2 K}{(\omega^2+K^2)C_0}, \tag{12}$$

where β_0 is the total static isothermal compressibility, K is the rate constant for return to equilibrium after a slight perturbation, C_0 is the phase velocity of sound at very low frequencies, and ω is the angular frequency.

Leonard's measurements indicated $\beta'/\beta_0 = 0.5\times10^{-4}$ and $K = 0.9\times10^{-4}$ sec^{-1} in 0.02 M $MgSO_4$ at 25°C.

Liebermann considered two possibilities of the chemical reaction—unimolecular and dissociation type. Corresponding to these types Liebermann derives the following equations for β_0'. For a reaction of the type $A \rightleftarrows B$,

$$\beta_0' = (V/RT)[\Delta V/V]^2 N(1-N), \tag{13}$$

where V is the volume of solution containing 1 M of solute, R is the gas constant, T is the absolute temperature, N is the fraction of molecules in state B at equilibrium, and ΔV is dV/dN. For a reaction of the type $AB \rightleftarrows A+B$,

$$\beta_0' = (V/RT)[\Delta V/V]^2[N(1-N)/(2-N)]. \tag{14}$$

Here N is the fraction of AB dissociated.

Liebermann concluded that anomalous absorption in $MgSO_4$ had its origin in a dissociation reaction and stated that for this reaction K is proportional to m while β_0' would vary as $m^{\frac{1}{2}}$, where m is the molar concentration.

According to Barthel[17] the concentration behavior of β_0' and K is represented as follows. For a reaction of the type,

$$A \underset{k_2}{\overset{k_1}{\rightleftarrows}} B,$$

$$K = k_1+k_2 \tag{15}$$

and

$$\beta_0' \propto k_1k_2(k_1+k_2)^{-2}m; \tag{16}$$

and for

$$AB \underset{k_2}{\overset{k_1}{\rightleftarrows}} A+B,$$

mostly dissociated,

$$K \simeq k_1 \tag{17}$$

$$\beta_0' \propto [(k_2/k_1)\nu_A\nu_B m]m; \tag{18}$$

and for

$$AB \underset{k_2}{\overset{k_1}{\rightleftarrows}} A+B,$$

only slightly dissociated,

$$K \simeq 2(k_1k_2\nu_A\nu_B m)^{\frac{1}{2}} \tag{19}$$

$$\beta_0' \propto [(k_2/k_1)\nu_A\nu_B m]^{-\frac{1}{2}}m, \tag{20}$$

where m represents the molar concentration, k_1 is the rate constant for the forward reaction, k_2 is the rate constant for the reverse reaction, and ν's are activity coefficients. Activity coefficients for ionic reactants generally decrease rapidly with increase of concentration. If $MgSO_4 \rightleftarrows Mg^{++}+SO_4^{--}$ is taken as the mechanism corresponding to the case $AB \rightleftarrows A+B$, mostly dissociated, the data of Harned and Owen[21] show that

[21] H. S. Harned and B. B. Owen, *The Physical Chemistry of Electrolytic Solutions* (Reinhold Publishing Corporation, New York, 1950).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the mean activity coefficient for the magnesium and sulfate ions varies as $m^{\frac{1}{2}}$ with the result that the concentration dependence approximately cancel out of the factor $\nu_A\nu_B m$ making β_0' proportional to m and K, independent of m even in the dissociation case, similar to unimolecular reaction.

Wilson[15] and Tamm and Kurtze[16a] have applied relaxation theory to chemical equilibrium and obtain the following expressions for the absorption coefficient per wavelength. For the unimolecular reaction

$$A \underset{k_2}{\overset{k_1}{\rightleftarrows}} B,$$

the absorption per wavelength is

$$\alpha\lambda = \frac{\pi(\Delta V)^2}{\beta_0 RT}\frac{CK}{(1+K)^2}\frac{\omega\tau}{1+\omega^2\tau^2}, \tag{21}$$

with the angular frequency of relaxation

$$1/\tau = k_1 + k_2. \tag{22}$$

In these equations C is the total concentration of the solute, ΔV is the difference between the partial molar volumes, $K = C_B/C_A = k_1/k_2$ is the equilibrium constant, k_1 and k_2 are the forward and reverse reaction rates, respectively, β_0 is the static compressibility, ω is the angular frequency, and τ is the relaxation time.

For the dissociation reaction

$$AB \underset{k_2}{\overset{k_1}{\rightleftarrows}} A + B,$$

the results are

$$\alpha\lambda = \frac{\pi(\Delta V)^2}{\beta_0 RT}\frac{C\delta(1-\delta)}{(2-\delta)}\frac{\omega\tau}{1+\omega^2\tau^2} \tag{23}$$

and

$$\begin{aligned} 1/\tau &= k_1 + 2C\delta\Pi k_2 \\ &= k_1\{1+[2(1-\delta)/\delta]\}, \end{aligned} \tag{24}$$

where δ is the fractional dissociation and Π is the mean activity coefficient product.

Bies[18] considers a small unit cube in a homogeneous volume of solution. Supposing that no molecules of solvent nor of solute get in or out of the cube and that the dimensions of the cube, which is in a plane sound field, are small compared to wavelength, then the rate reaction for a dissociation reaction $AB \rightleftarrows A + B$ can be written in terms of the numbers of molecules and ions per unit volume as

$$dn_1/dt = k_1 n - k_2 f_\pm^2 n_1 n_2, \tag{25}$$

where $AB = C(1-\delta) = n/N$, $A = C\delta = n_1/N$, $B = C\delta = n_2/N$, and $f_\pm^2$ = mean squared activity coefficient provided C is the total concentration of A in either the molecular or the ionized state and δ, the fraction of A in ionized state.

At equilibrium

$$dn/dt = -dn_1/dt = -dn_2/dt = 0. \tag{27}$$

Here k_1 and k_2 are assumed to be independent of concentration while $f_\pm^2$ is assumed to be a function of concentration. All the parameters n, n_1, n_2, k_1, k_2, and $f_\pm^2$ are assumed to be pressure dependent and have a harmonic time dependence of the form $\exp i\omega t$ in a harmonic sound field. When sound waves pass through the medium, the concentration of the molecules and the ions varies because of the variation in their numbers and the volume. The contribution of the latter to absorption is, however, negligible.

Thus, the general irreversible rate equation may be represented by a Taylor series in terms of small variations in all of the parameters.

If we consider only linear terms,

$$\begin{aligned} i\omega\Delta n_1 = {} & n\Delta k_1 - f_\pm^2 n_1 n_2 \Delta k_2 + k_1 \Delta n \\ & - k_2 f_\pm^2 (n_1\Delta n_2 + n_2\Delta n_1) - k_2 n_1 n_2 \Delta f_\pm^2 \\ & - (k_1 n - 2k_2 n_1 n_2 f_\pm^2)\Delta v. \end{aligned} \tag{28}$$

By using the mass action equilibrium law

$$K = k_1/k_2 = (f_\pm^2 n_1 n_2)/n, \tag{29}$$

we get

$$n\Delta k_1 - f_\pm^2 n_1 n_2 \Delta k_2 = k_2 f_\pm^2 n_1 n_2 (\Delta K/K). \tag{30}$$

From well-known thermodynamic relations

$$\partial(\Delta F_0)/\partial p = -\Delta V_0 \tag{31}$$

and

$$\Delta F_0 = -RT \ln K, \tag{32}$$

the following expression for ΔV_0 is obtained:

$$\Delta V_0 = (-RT/K)(\partial K/\partial n)(\partial n/\partial p)_T. \tag{33}$$

Here ΔV_0 is considered to be an empirical constant as the associated energy change ΔF_0 represents the free energy change when all the reactants are in their standard state.

The contribution β' to the isothermal compressibility due to a perturbation of the dissociation process is

$$\beta' = -(\partial v/\partial n)(\partial n/\partial p)_T. \tag{34}$$

We define

$$\Delta V = N(\partial v/\partial n)_T, \tag{35}$$

$$\beta' = -(\Delta V/N)(\partial n/\partial p)_T. \tag{36}$$

Hence,

$$\begin{aligned} \Delta V_0 &= (+RT/K)(\Delta K/\Delta n)(N\beta'/\Delta V) \\ \Delta K/K &= +[(\Delta V_0)(\Delta V)]\Delta n/(N\beta' RT) \end{aligned} \tag{37}$$

or

$$= (W\Delta n/N\beta' RT), \tag{38}$$

where $W = (\Delta V_0)(\Delta V)$. Thus

$$n\Delta k_1 - \Delta k_2 f_\pm^2 n_1 n_2 = (nk_1 W\Delta n/N\beta' RT). \tag{39}$$

To estimate the variation in the unit volume with the passage of sound waves we note that the net change in volume Δv must lag behind the acoustic pressure p

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

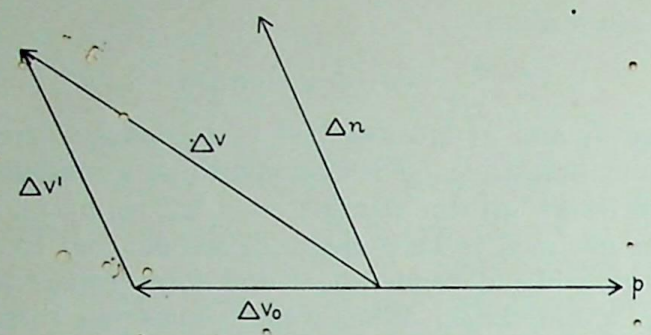

FIG. 1. Vectorial representation of the variations in volume, pressure, and number of molecules n, with the passage of a sound wave.

since this gives the work done on the system as positive. Δv_0 is the variation in volume of the solvent which is assumed dissipationless so that it lags behind the acoustic pressure by 180°. The variation in volume $\Delta v'$ due to a shift in the equilibrium is assumed to be in phase with the variation in the number of molecules Δn. The resultant change in the volume of the solution is Δv. A decrease in volume associated with the dissociation process has been assumed. The foregoing can be represented vectorially in Fig. 1.

From Fig. 1 it follows that

$$\Delta v = -(\beta_0+\beta')\gamma p \tag{40}$$

$$\Delta v' = -\beta'\gamma p. \tag{41}$$

Since the process is assumed to be adiabatic, the ratio of the specific heats γ has been introduced.

Also it may be assumed that

$$\Delta v' = (\partial v/\partial n_2)\Delta n_2 = (\Delta V)\Delta n/N.$$

Eliminating $\Delta v'$ and γp between the last three expressions, we have

$$\Delta v = \Delta V(\beta_0+\beta')\Delta n/N\beta'. \tag{42}$$

To estimate $\Delta f_\pm^2$, consider a function F defined such that

$$F = -(Z_1^2+Z_2^2)d(\ln f_\pm^2)/d\Gamma, \tag{43}$$

where Γ is the ionic concentration and is given by

$$\Gamma = N^{-1}\sum_{i=1}^{i=4} n_i z_i^2. \tag{44}$$

Thus, it can be shown that

$$\Delta f_\pm^2 = -f_\pm^2 F(\Delta n/N - \Gamma'\Delta v), \tag{45}$$

where $\Gamma' = \Gamma/(Z_1^2+Z_2^2)$.

After substituting Eqs. (39), (42), and (45) into Eq. (28) and canceling out Δn, the following expression for β' is obtained:

$$\beta' = k_1 n N^{-1}[W(RT)^{-1} - (\Delta V)\beta_0(F\Gamma'-1)][i\omega - K]^{-1},$$

where

$$K = k_1[1+n(n_1^{-1}+n_2^{-1}) + nN^{-1}(F+\Delta V - F\Gamma'\Delta V)]. \tag{46}$$

If we assume that (ΔV) is very small, such that $(\Delta V)\ll F$ and $(\Delta V)\ll(\Delta V_0)$, all the terms containing (ΔV) may be neglected. Thus,

$$\beta' = [k_1 nW/NRT(i\omega - K)],$$

where

$$K = k_1[1+n(n_1^{-1}+n_2^{-1}-FN^{-1})]. \tag{47}$$

β' has a maximum value at $\omega = K$ and thus K is the relaxation frequency.

The maximum value of $(2\alpha\lambda)$ is given by

$$(2\alpha\lambda)_{\max} = -2\pi_{\max}\,\mathrm{Im}(\beta'/\beta_0),$$

where

$$\beta' = nk_1W/NRT(i\omega - K).$$

Thus, the maximum value is

$$(2\alpha\lambda)_{\max} = (\pi nk_1W/NRTK\beta_0). \tag{48}$$

Expressing in terms of concentration and the degree of dissociation δ, the maximum value of the energy absorption per wavelength is given by

$$(2\alpha\lambda)_{\max} = \mu_{\max} = [\pi C(1-\delta)k_1W/K\beta_0RT] \tag{49}$$

and

$$K = k_1[1+(1-\delta)\delta^{-1}(2-Fc\delta)]. \tag{50}$$

As the function F always appears as $Fc\delta$, it is better to consider the latter. The function F, as expressed earlier, is

$$F = -(Z_1^2+Z_2^2)(d/d\Gamma)(\ln f_\pm^2) = -8(d/d\Gamma)(\ln f_\pm^2),$$

where $Z_1 = -Z_2 = 2$ and

$$\ln f_\pm^2 = -4.606S\Gamma^{\frac{1}{2}}(1+A\Gamma^{\frac{1}{2}})^{-1} \tag{51}$$

according to Debye-Hückel theory. If the ionic diameter is considered equal to 3.08 A, S and A are given by

$$S = 5.132\times10^6(DT)^{-\frac{3}{2}}, \tag{52}$$

$$A = 109.6(DT)^{-\frac{1}{2}}, \tag{53}$$

where D is the dielectric constant, and T the temperature. Thus

$$Fc\delta = 18.424Sc\delta\Gamma^{-\frac{1}{2}}(1+A\Gamma^{\frac{1}{2}})^{-2}. \tag{54}$$

Eigen[22] has considered the general case which is characterized by a consecutive reaction of the form given below:

$$A^{++}+B^{--} \rightleftarrows (AB)_1 \rightleftarrows (AB)_2 \rightleftarrows \cdots \rightleftarrows (AB)_n.$$

According to him the recombination of oppositely charged ions is hindered by hydration layers and can not be treated as a one-step mechanism. It has to proceed stepwise. This system has a spectrum of relaxation times, in which the number of time constants corresponds to the number of independent steps. The relaxation times have to be calculated from the whole

[22] M. Eigen, Discussions Faraday Soc. 17, 194 (1934); 24, 25 (1957); *Chemische Relaxation* (Steinkopf, Darmstadt, 1958); Eigen, Kurtze, and Tamm, Z. Elektrochem. 57, 103 (1953).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

system of linearized rate equations. For example, in the case of a reaction consisting of two steps,

$$\underset{\text{I}}{A^{++}}+B^{--}\underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}}\underset{\text{II}}{AB'}\underset{k_{32}}{\overset{k_{23}}{\rightleftarrows}}\underset{\text{III}}{AB}$$

with $k_{12}, k_{21} \gg k_{23}, k_{32}$, the linearized rate equations are

$$\begin{aligned}\dot{x}_1&=-k_{12}'x_1+k_{21}x_2\\ \dot{x}_2&=k_{12}'x_1-(k_{21}+k_{23})x_2+k_{32}x_3\\ \dot{x}_3&=k_{23}x_2-k_{32}x_3,\end{aligned}\tag{55}$$

where $\delta C_B=\delta C_A=x_1$, $\delta C_{AB'}=x_2$, $\delta C_{AB}=x_3$, and $k_{12}'=k_{12}(\bar{C}_A+\bar{C}_B)$, where the $\bar{C}$'s are the equilibrium concentrations.

The transformation to a new system, $\dot{y}_i=-y_i/\tau_i$, where y_i is a new set of concentration variables instead of the given variables x_i and τ_i, the corresponding relaxation time, may be written in the vectorial forms

$$\mathrm{y}=M\mathrm{x}$$

and

$$\mathrm{x}=M^{-1}\mathrm{y},\tag{56}$$

where the matrices M and M^{-1} are given by

$$M=\begin{vmatrix}1 & 1 & 1\\ \dfrac{1}{1+A} & \dfrac{1}{1+A} & \dfrac{-A}{1+A}\\ -\dfrac{k_{12}'}{k_{12}'+k_{21}} & \dfrac{k_{21}}{k_{12}'+k_{21}} & 0\end{vmatrix}$$

$$M^{-1}=\begin{vmatrix}\dfrac{k_{21}k_{32}}{k_{12}'k_{23}} & \dfrac{1}{1+A} & \dfrac{k_{21}}{k_{12}'+k_{21}}-1\\ \dfrac{k_{32}}{k_{23}} & \dfrac{1}{1+A} & \dfrac{k_{12}'}{k_{12}'+k_{21}}\quad 1\\ \dfrac{1}{1+A} & -1 & 0\end{vmatrix}$$

with

$$A=(k_{32}/k_{23})[1+(k_{21}/k_{12}')].$$

The relaxation times result as eigenvalues of the functional equation

$$\frac{1}{\tau_1}=0,\quad \frac{1}{\tau_2}=\frac{k_{12}'(k_{23}+k_{32})+k_{21}k_{32}}{k_{12}'+k_{21}},\quad \frac{1}{\tau_3}=k_{12}'+k_{21}.\tag{57}$$

The relaxing parts of the compressibility are given by

$$\beta_{0(2)}'=\frac{C_0\beta(1-\beta)}{2-\beta}\,\frac{1+(k_{12}'/k_{21})}{1+(k_{32}/k_{23})}\,\frac{(\Delta V_2)^2}{RT},$$

$$\Delta V_2=\Delta V_{\text{II}-\text{III}}+\Delta V_{\text{I}-\text{II}}\frac{k_{21}}{k_{12}'+k_{21}};$$

and

$$\beta_{0(3)}'=\frac{C_0\beta(1-\gamma)}{2-\gamma}\,\frac{(\Delta V_3)^2}{RT},\quad \Delta V_3=\Delta V_{\text{I}-\text{II}},\tag{58}$$

where $\Delta V_{\text{I}-\text{II}}=V_A+V_B-V_{AB'}$, $\Delta V_{\text{II}-\text{III}}=V_{AB'}-V_{AB}$.

β and γ are degrees of dissociation; $\beta=C_A/C_0$, $(1-\beta)=(C_{AB'}+C_{AB})/C_0$, $\gamma=C_A/(C_0-C_{AB})$, $(1-\gamma)=C_{AB'}/(C_0-C_{AB})$.

The excess absorption per wavelength is given by

$$(\alpha\lambda)=\frac{\pi}{\beta_0}\left[\beta_{0(2)}'\frac{\omega\tau_2}{1+\omega^2\tau_2^2}+\beta_{0(3)}'\frac{\omega\tau_3}{1+\omega^2\tau_3^2}\right].\tag{59}$$

If $k_{12}', k_{21} \gg k_{23}, k_{32}$, the first step of the reaction is identical with the relaxation effect due to τ_3. For $C_{AB}\to 0 (\gamma=\beta=\delta)$ it becomes identical with the binary one-step equilibrium treated by Bies. The other effect (τ_2) corresponds to the final equilibrium between the state AB and the two states A^{++}, B^{--} and AB'. The relaxation time τ_2 is almost independent of concentration, except in a small transition range at concentrations C_A for which $k_{12}'\approx k_{21}$. Such a treatment seems to describe the experimental facts in a more extended concentration range which Bies's theory fails to do. It could not explain the behavior for concentrations above 10^{-2} M, where the relaxation time as well as the absolute value of $(\alpha\lambda/C)$ becomes almost independent of concentration.

(b) Activation Energy for the Rate Process

The temperature dependence of the relaxation frequency may be utilized to determine an experimental activation energy for the rate process.

Consider the reaction $A\to M'\to B$ where M' represents the activated or transition state for the reaction.

According to Eyring's reaction rate theory, the specific rate for the forward reaction is given by

$$k=(k'T/h)(C'/C_A)=(k'T/h)K',\tag{60}$$

where K' is the equilibrium constant for the activation reaction, k' is Boltzmann's constant, h is Planck's constant, T is temperature, and C' and C_A are the concentrations of the indicated species. $k'T/h$ represents the rate at which molecules pass from the activated state. The true equilibrium constant for the activation reaction is

$$K_0'=K'\nu'/\nu_A,\tag{61}$$

where ν' and ν_A are the activity coefficients. Then the reaction rate is given by

$$\begin{aligned}k&=(k'T/h)(\nu_A/\nu')K_0'\\ &=(k'T/h)(\nu_A/\nu')\exp(-\Delta F^{0\prime}/RT),\end{aligned}\tag{62}$$

where $\Delta F^{0\prime}$ is standard free energy of activation.

Hence the specific rates for the forward reaction and

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

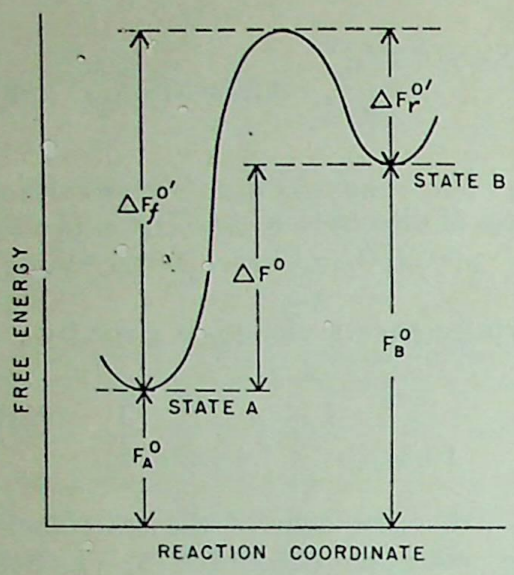

FIG. 2. A two-state potential-energy diagram.

the reverse reaction are

$$k_f = (k'T/h)\exp(-\Delta F_f^{0'}/RT) \quad (63)$$

$$k_r = (k'T/h)\exp(-\Delta F_r^{0'}/RT) \quad (64)$$

considering the activity coefficients as unity. Figure 2 illustrates the relation between the energies in the three states.

The relaxation time τ is given by

$$\tau = 1/(k_f + k_r),$$

where

$$k_f + k_r = (k'T/h)[\exp(-\Delta F_f^{0'}/RT) + \exp(-\Delta F_r^{0'}/RT)].$$

If we assume that $k_f \ll k_r$,

$$\tau = 1/k_r = (h/k'T)\exp(\Delta F_r^{0'}/RT). \quad (65)$$

Hence the relaxation frequency f_m is given by

$$f_m = (k'T/2\pi h)\exp(-\Delta F_r^{0'}/RT). \quad (66)$$

Assuming activation energy independent of the temperature

$$\log(f_m/T) = -(\Delta H_r'/RT)\log e + \text{constant}$$

$$\Delta F_r^{0'} = \Delta H_r' - T\Delta S_r, \quad (67)$$

where $\Delta H_r'$ is the enthalpy and $\Delta S_r'$ is the entropy of activation.

The activation enthalpy can be obtained from the slope of the curve $\log(f_m/T)$ *vs* $1/T$. Since the pdV term is negligible, ΔH is approximately the activation energy.

(c) Different Mechanisms

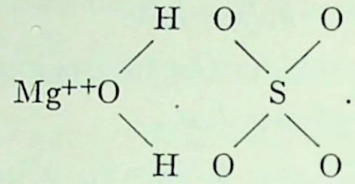
(a) The simplest dissociation reaction for the primary relaxation, which has been suggested by Liebermann,[3] and supported by Leonard, Bies,[18] and Verma and Kor[23] for a 2–2-valent metallic sulfate MSO_4 is

$$MSO_4 \rightleftarrows M^{++} + SO_4^{--}. \quad (68)$$

(b) Barthel[16] has suggested the following mechanism:

$$M^{++} + H_2O \rightleftarrows MOH^+ + H^+. \quad (69)$$

(c) Tamm and Kurtze[19] assume the existence of a complex of the form MeR, H_2O where Me=metal, R=radical. For example, in the case of $MgSO_4$ the complex is represented by



For this complex two different possibilities of dissociation are assumed.

(1) The formation of two univalent ions

$$(MgSO_4, H_2O) \rightarrow MgOH^+ + HSO_4^- \quad (70)$$

which each split up in a subsequent step

$$MgOH^+ + HSO_4^- \rightarrow Mg^{++} + OH^- + H^+ + SO_4^{--}. \quad (71)$$

The first step is considered to be acoustically inefficient. The two dissociation processes are independent of each other and explain the two relaxation frequencies which are observed. For example, in $MgSO_4$ the dissociation of $MgOH^+$ explains the relaxation frequency at 130 kc and the dissociation of HSO_4^- the second relaxation frequency at 200 Mc.

(2) Another possibility exists in the separation of either of the metal ion or of the radical ion from the complex in the form

$$MgSO_4, H_2O \rightarrow Mg^{++} + H_2O \cdot SO_4^{--}$$
$$\rightarrow Mg \cdot H_2O^{++} + SO_4^{--}. \quad (72)$$

(d) Smithson and Litovitz[20] assume the reaction to be between two dipole molecules, i.e., the reaction between the solute molecules (ion pairs) and the dipole solvent. The great excess of the solvent assures that this reaction is of first order. The reaction might be of the type

$$MnSO_4 + H_2O \rightleftarrows Mn \cdot H_2O^{++} + SO_4^{--}. \quad (73)$$

(e) According to Eigen,[22] the simplest possible mechanism allowing an explanation of all hitherto found results may be represented by the following scheme:

$$\underset{\text{I}}{A^{++} + B^{--}} \rightleftarrows \underset{\text{II}}{AB'} \rightleftarrows \underset{\text{III}}{AB''} \rightleftarrows \underset{\text{IV}}{AB'''}. \quad (74)$$

The first equilibrium (I-II) corresponds to diffusion-controlled steps of interaction of the completely hydrated ions, which is present in all electrolytic solutions, especially in those which do not show any detectable absorption below 300 Mc. A relaxation effect due to this interaction should be expected at frequencies higher than 10^3 Mc. The relaxation effects found in 2–2-valent electrolytes are connected with further consecutive re-

[23] G. S. Verma and G. K. Kor, Proc. Phys. Soc. (London) 72, 81 (1958); J. Chem. Phys. 29, 9 (1958).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

action steps in the above scheme (II-III,III-IV). The physical reality of such discrete steps is provided by the fact that the maxima, at least at lower frequencies, have the shape of monochromatic relaxation curves. However, there exists the possibility of more complicated mechanisms in which all the relaxation steps are not detectable.

(f) Recently Verma[24] has proposed a mechanism which shows that when H_2O is replaced by D_2O as the solvent, the primary relaxation frequency should not change, whereas the rate of process responsible for the secondary relaxation is altered considerably. The mechanism is as follows:

$$MSO_4, nH_2O \rightleftarrows [M, (n-1)H_2O]^{++} + [SO_4, H_2O]^{--} \quad (a)$$

$$M^{++} + 2H_2O \rightleftarrows (MOH)^+ + (H_3O)^+ \quad (b)$$

$$SO_4^{--} + (H_3O)^+ \rightleftarrows (HSO_4)^- + H_2O \quad (c)$$

$$MOH^+ + (HSO_4) \rightleftarrows MSO_4 + H_2O. \quad (d)$$

The process (a) with higher activation energy corresponds to the primary relaxation frequency and the process (d) with the lower activation energy to the secondary relaxation frequency. Processes (b) and (c) are acoustically inefficient.

III. METHODS FOR MEASURING THE ABSORPTION

The methods for measuring sound absorption can be classified into two groups depending upon the technique utilized, namely, (1) progressive wave technique and (2) standing wave technique. In the former, absorption is determined from the decrement in the intensity of the plane progressive sound waves governed by the relation

$$I_x = I_0 e^{-2\alpha x}, \quad (75)$$

where I_0 is the intensity at the source, I_x the intensity at a distance x from the source and α the attenuation constant. This is only applicable to measurements above 1 Mc as the absorption, being proportional to the square of the frequency, decreases to such an extent below 1 Mc that the measurements are not reliable. How low is the absorption in water at frequencies below 1 Mc is evident from the fact that the amplitude of a plane wave is reduced only by 10% in a distance of 1 km. Thus, in order to have accurate and reliable results there should be very large volumes of the liquid available in the laboratory, which is hardly possible on such a large scale. Moreover, in order to have the proper directivity of the sound beam, the transducer should be very large.

These difficulties are considerably reduced if absorption is measured by the standing wave technique. In this the absorption is determined from the decay with time of the energy E of a standing wave between the boundaries of the liquid. The decay is governed by the relation

$$E_t = E_0 e^{-2\delta t}, \quad (76)$$

where $\delta = \alpha c$, c being the velocity of propagation of sound waves. The difficulty here lies in the elimination of the boundary losses which influence the decay constant considerably. The decay constant can either be determined by the resonance method or the reverberation method. In the resonance method the decay constant is determined from the decay time of only a single mode of oscillation of the system consisting of the liquid plus the container, whereas in the reverberation method the system is excited to a large number of normal modes of oscillation.

(a) Methods Based upon Progressive Wave Technique

Methods which are based upon the progressive wave technique can be further classified into three main groups which are (1) mechanical methods, (2) optical methods, and (3) electrical methods.

(1) *Mechanical Methods*

The mechanical method, which is in frequent use, depends upon the measurement of sound radiation pressure. When sound waves meet an obstacle the pressure at the front differs from that at the back. The pressure behind the obstacle is assumed to be the pressure in the medium at rest, i.e., in the absence of the sound beam. According to Lord Rayleigh the difference of the pressure, which is known as radiation pressure, is given by

$$S = \tfrac{1}{2}(\gamma+1)(I/C), \quad (77)$$

where γ is the ratio of specific heats, C the velocity, and I the intensity of sound waves. Thus if the radiation pressure is measured at different distances the absorption coefficient for the intensity is easily known from the variation with distance.

The actual radiation pressure, however, as encountered in an acoustic beam under ordinary experimental conditions is different from Rayleigh's pressure. Mean radiation pressure $\bar{P}$ per unit area of a plane compressional wave, however, is defined by

$$\bar{P} = \bar{p} + \langle \rho u^2 \rangle, \quad (78)$$

where p is the excess pressure of the acoustic waves, ρ the density of the medium, and u the velocity. As a generalization of Eq. (78), the mean radiation pressure upon an obstacle of arbitrary shape in an acoustic field can be written

$$\langle \mathbf{P} \rangle = \bar{p}\mathbf{n} + \langle \rho \mathbf{u}(\mathbf{u}\cdot\mathbf{n}) \rangle, \quad (79)$$

where $\mathbf{u}$ now stands for the vector of the velocity $\mathbf{u}(x,y,z)$ and $\mathbf{n}$ is the vector of the inner normal on the surface element under consideration. According to

[24] G. S. Verma, J. Chem. Phys. 29, 1186 (1958).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Borgnis,[25] the radiation pressure for a beam of finite width in any fluid and on any plane reflecting surface is given by

$$P=2\langle\langle E\rangle\rangle_{\text{kin}}=\langle\langle E\rangle\rangle_{\text{total}}+(\langle\langle E\rangle\rangle_{\text{kin}}-\langle\langle E\rangle\rangle_{\text{pot}}). \quad (80)$$

At small amplitudes $\langle\langle E\rangle\rangle_{\text{pot}}=\langle\langle E\rangle\rangle_{\text{kin}}$ and, therefore,

$$2\langle\langle E\rangle\rangle_{\text{kin}}=\langle\langle E\rangle\rangle_{\text{total}}=\bar{E}_i(1+\beta^2), \quad (81)$$

where $\bar{E}_i$ is the mean energy density of the incident waves and β the reflection coefficient. Hence

$$\bar{P}=2\bar{E}_{\text{kin}}=\bar{E}_i(1+\beta^2)$$
$$=\tfrac{1}{2}\rho_0\omega^2\xi_0^2(1+\beta^2)=(I/C)(1+\beta^2). \quad (82)$$

The above expression is valid both in liquids and gases, when terms of third and higher order in $k\xi_0=(2\pi/\lambda)\xi_0$ are excluded.

There are various ways to measure the radiation pressure. One way uses a torsion balance, which carries on one side a plate or cone which is struck by sound waves, while on the other side weights can be placed to balance the upthrust upon the plate or cone. Sometimes the displacement of the plate or the bead at the end of a long wire when a sound beam traveling horizontally impinges upon it, is used as a measure of sound radiation pressure. Another convenient way to measure the intensity uses a movable vane forming one plate of the condenser, and variations in the capacitance of the system are noted. W. Rufer,[26] employing the above technique, successfully measured the absorption in a large number of electrolytes over a frequency range of 2.9–8.85 Mc for concentrations of 10% and 1 mole/liter.

Ultrasonic absorption in aqueous solutions of $MnSO_4$ has been studied by the pressure balance method in the frequency range (12–43 Mc) by Smith, Barret, and Beyer[27] with the purpose of examining the behavior of aqueous solutions at higher frequencies.

McNamara and Beyer[28] have suggested a variation of radiation pressure method which possesses an accuracy comparable to that of pulse and optical methods. It consists in modulating the transducer at an audio-frequency and detecting the consequent low-frequency variations in the radiation pressure with a condenser microphone.

According to Markham, Beyer, and Lindsay,[29] the measurements with this method below 3 Mc are not reliable since difficulties arise such as those due to retarding forces which might be comparable to the forces which are being measured, specular reflections from the walls of the container, hydrodynamic flow, failure of the detector to intercept the divergent sound beam at low frequencies, and cavitation at high intensities.

Another convenient and accurate method of measuring the absorption coefficient is provided by the velocity of acoustic streaming in a fluid. It is now a well-established fact that there exists a time-independent gradient of radiation pressure associated with the propagation of plane progressive waves of sound through an attenuating fluid medium. This constant gradient produces an acceleration of the fluid and hence streaming. Viscous forces arise which resist the streaming till the steady state condition is reached when these forces exactly balance the gradient of radiation pressure. According to Eckart[30] (1948), Liebermann[31] (1949), Karim and Rosenhead[32] (1952), and Karim[33] (1953), measurements of the streaming velocity provides an independent method of determining the ratio of the second coefficient of viscosity to coefficient of shear viscosity. On the other hand, Nyborg[34] (1953) and Piercy and Lamb[35] (1954) have established both by theory and experiments that the sound attenuation rather than the second viscosity is the factor responsible for streaming. This conclusion was originally pointed out by Fox and Herzfeld[36] (1950). Markham[37] (1952) too supported this view.

The experimental arrangement for measuring the sound absorption in liquids at frequencies around 1 Mc is shown in Fig. 3. The main tube is completely filled by the beam of progressive sound waves and the side tube provides the return path of the streaming where progressive sound waves do not extend.

According to Poiseuille, the flow velocity v_0 of a fluid along the axis of a tube of radius r and length l is given by

$$v_0=(\Delta p r^2/4\eta l), \quad (83)$$

where Δp is the difference in pressure between the ends of the side tube and η is the coefficient of shear viscosity of the fluid, provided the effect of the corners of the side

tube on the flow is neglected, which is true for small velocities of streaming. The difference in pressure Δp arises because of the change in radiation pressure due to attenuation in sound waves over a length l in the main tube. Thus, the streaming velocity on the axis of the tube is given by

$$v_0 = \frac{E_0 r^2 (1 - e^{-2\alpha l})}{4\eta l}, \quad (84)$$

where E_0 is the acoustic energy density at the entrance to the side tube nearer the source, which is experimentally known by using the radiation pressure vane. Small aluminum particles are suspended in the liquid, and the velocity of flow is determined by noting their motion through a microscope and η is taken from published tables. According to Piercy, absorptions accurate within 5% can be measured. Recently Hall and Lamb[38] have extended the frequency range of this method down to 100 kc, with an accuracy of ±11% at 130 kc.

(2) *Optical Method*

The optical method is based on the Debye-Sears effect and was first of all developed by Bicquard.[39] Recently many improvements in the general technique have been made by Burton,[40] Willis,[41] and Sette.[42] Kurtze and Tamm used the optical method for the measurement of ultrasonic absorption in electrolytic solutions in the frequency range 3–200 Mc.

The experimental arrangement used by Tamm and Kurtze for the frequency range 3–15 Mc is shown in Fig. 4. Sound beam from the quartz crystal is crossed perpendicularly by a parallel beam of light which, by moving the mirrors can be shifted along it. The liquid tank is 1 m in length and has rubber wedges placed at its ends to avoid the formation of standing waves. The first order of the resulting diffraction pattern is given to a photoelectric cell which is followed by a multiplier. The output of this multiplier is connected to a logarithmic level recorder. The sound is modulated and the multiplier is also tuned to the modulation frequency. In the frequency range 20–100 Mc the principle of the method is the same except that the vessel itself is moved instead of a light beam.

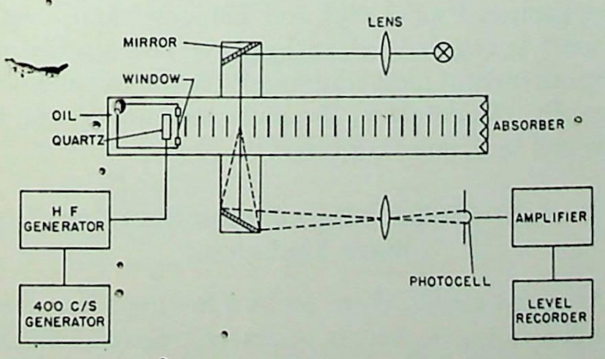

FIG. 4. Sound absorption measurement by the optical method.

(3) *Electrical Methods*

There are three general electrical methods for measurement of ultrasonic absorption in fluids based upon the progressive wave technique. They are (1) interferometric methods, (2) direct methods, and (3) pulse method.

The interferometric methods consist essentially of a plane quartz crystal which acts as a transducer and a reflector set parallel and opposite to the radiating face of the crystal. The distance between them can be varied either by moving the reflector or the transducer itself. Sound waves emanating from the crystal are reflected from the reflector, and stationary waves are formed in the space in between them. If the reflected waves reaching the radiating face are 180° out of phase with the signal just coming out, distrubance just at the radiating face will be reduced to zero and the plate current in the output stage of the driver oscillator will increase. As the reflector is moved towards or away from the source, plate current increases every time the reflector is moved away a half wavelength. According to Pielemeier,[43] the current reading in the output stage of the driving oscillator is proportional to excess pressure in the sound beam at the face of the crystal. Thus, if x represents the distance through which the reflector is moved, the increase in path length will be $2x$ and the pressure of the returning wave is decreased by $e^{-2\alpha x}$. Hence the absorption can be determined by noting the current at two maxima and its decrement with distance.

The whole picture is not so simple, for it has been shown by Hubbard[44] and others that the current is a complicated function of the absorption coefficient, the reflection coefficient of the reflecting surface, and the distance moved by the reflector. Hubbard used a buffer amplifier between the oscillator and the interferometer to reduce the effects of load variations on the frequency of the oscillator. Alleman[45] showed that lack of perfect alignment between the transducer and the reflector leads to erroneous results. Pumper[46] has discussed the departure of the sound beam from a plane wave. Some uncertainty regarding the reflection also remains, as it is alleged to be modified by heat conduction. This method has been used by several workers[47–49] including the author.[50]

In the *direct method* the excess pressure or the in-

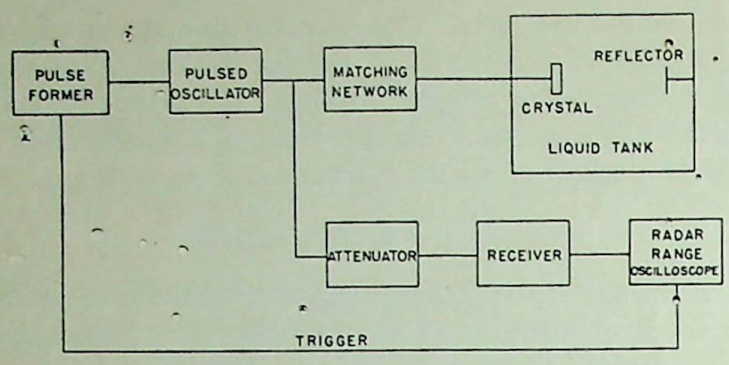

FIG. 5. Sound absorption measurement by the pulse method.

tensity is measured by the microphone which is placed along the axis of the sound beam. The method is not so simple as it appears to be, as many difficulties are associated with it. In the case of the transducer which is assumed to be a pistonlike source, Fraunhofer diffraction takes place within a distance of a^2/λ from the crystal, where a is the radius of the transducer and the typical Fresnel pattern is observed at much greater distances. King[51] and Born[52] have deduced approximate theoretical expressions for the radiation field which can be used for the determination of the absorption coefficient. Correction has to be made for the finite size of the microphone in case its dimensions are not small compared to the wavelength. Standing waves as usual offer a problem which can be reduced by tilting the microphone, so that the face of the microphone is not perpendicular to the axis of the beam.

The direct method has been successfully utilized by Smith, Barrett, and Beyer[27] on the determination of ultrasonic absorption in $MgSO_4$ in the neighborhood of 3 Mc. The detector consisted of a barium titanate crystal connected in parallel with a selenium detector. These two units are mounted in the edge of a probe and connected with a Rubicon galvanometer. The response of the rectifier as read on the galvanometer is proportional to the average intensity of the sound beam over crystal face.

Any method which utilizes continuous waves suffers from two defects. First, there always exists the possibility of stationary waves being formed, which leads to erroneous results of absorption, and secondly, local heating due to sound energy in the main beam may cause temperature waves from the center of the sound beam, which is at a higher temperature, towards the edges of the beam, which is comparatively at a lower temperature. Because of the change in temperature, the temperature recorded by the thermometer kept at a certain distance from the main beam is not the true temperature at which absorption is being measured. But these difficulties are removed in the pulse method.

The experimental arrangement used by Pellam and Galt[53] for the measurement of ultrasonic absorption in liquids is shown in Fig. 5. The arrangement consists of a quartz transducer and polished reflector set up parallel to each other. The pulsed radio-frequency voltage at 15 Mc with a repetition rate of the order of 1000 per sec and pulse width of 1 μsec was applied to the quartz crystal. Thus the average power is only 1/1000 that of a continuous signal at the same amplitude. The same crystal which acts as a transducer is used as a receiver. The distance between the crystal and the reflector can be arranged such that the reflected signal arrives at the instant when there is no transmission of pulse so that stationary waves are not formed. "The scheme is essentially to use the liquid sample as a storage medium for short sound pulses and to measure the time delay and the attenuation undergone by the sound in traversing a known path within the liquid. The acoustical pulses are generated from electrical pulses by means of a crystal transducer and are converted back to electrical form upon completing a transit through the liquid. The effect of changing the acoustic length can be compensated for electrically. Hence, the measured delay produced by the increase in path length gives a measure of the sound velocity; the attenuation which must be removed from the electrical circuit to balance the acoustical losses in additional distances provides a measure of the absorption. With the help of suitable electronic equipment the central and the reflected pulses are compared on an oscilloscope. The initial pulse is generally allowed to pass through a calibrated attenuator and the attenuation required to reduce the size of the initial pulse to match that of the reflected pulse measures the power loss in transmission plus losses due to reflection. When the reflector is moved through a distance x it will mean an increase in path length by $2x$. Thus, if the attenuation noted is plotted against the distance $2x$, the absorption coefficient can be determined from the graph."[53]

Litovitz and his associates have studied ultrasonic absorption in $MnSO_4$ and NH_4OH by the pulse method. Lamb and his associates have utilized pulse technique in studying the relaxation due to rotational isomerism in unsaturated aldehydes and ketones[54] and triethylamine.[55] Young and Petrauskas have also studied rotational isomers of methylbutanes[56] by the pulse method. Recently, the details of the pulse technique have been reviewed by Lamb and others.[57]

(b) Methods Based upon Standing Wave Technique

As stated earlier, there are two methods based upon standing wave technique—namely, the reverberation method and the resonance method. These are frequently

used for the measurement of ultrasonic absorption below 1 Mc. The reverberation technique has been used by Mulders,[58] Moen,[59] and Tamm and Kurtze.[16a] The resonance method has been used by Leonard, Bies, and Tamm and Kurtze.

(1) *Resonance Method*

The *resonance method* differs from the reverberation method in several aspects, the most important of which is the use of a single resonant mode of the spherical resonator. "A small piezo-electric crystal transducer attached to the wall of a liquid-filled spherical resonator is used to excite one of the natural modes of the resonator until the sound intensity reaches a sufficiently high level. The transducer is then switched from the exciting amplifier to a receiving amplifier. The sound energy level now in the resonator decays exponentially at a rate determined by the energy losses in the system. A high-speed power level recorder which plots the logarithm of the decaying receiver output voltage against time, yields a straight decay curve, the slope of which is easily measured. If the losses of the sound energy at the walls and supports of the resonator are negligible, the decrease in sound level results only from the absorption of sound in the contained liquid, and thus the decay rate is a measure of the sound absorption coefficient for the liquid. The decay rate in decibels per second divided by the sound velocity yields the plane wave absorption coefficient in decibels per unit of distance." The schematic diagram of the apparatus is shown in Fig. 6.

The system is normally in the receiving condition as shown. Boundary losses which are an important factor can be eliminated by subtracting the decay constant corresponding to the case when the resonator is filled with a standard liquid. Thus the true absorption of the electrolyte is known from

$$\alpha_{\text{electrolyte}}=\alpha-\alpha_{\text{standard}}=(\delta-\delta_{\text{standard}})/C. \quad (85)$$

The advantages of having a spherical glass resonator are many. First, the deformation and wall frictional losses are minimized by making the walls extremely thin, which is possible in this stable shape. Secondly, there exist certain radial modes of vibrations of which boundary losses can be neglected. Thirdly, it is possible to estimate theoretically the boundary losses considering the deviations of the sound field in the case of an ideal spherical resonator. Bies used round-bottom twelve-liter Pyrex boiling flasks as resonators.

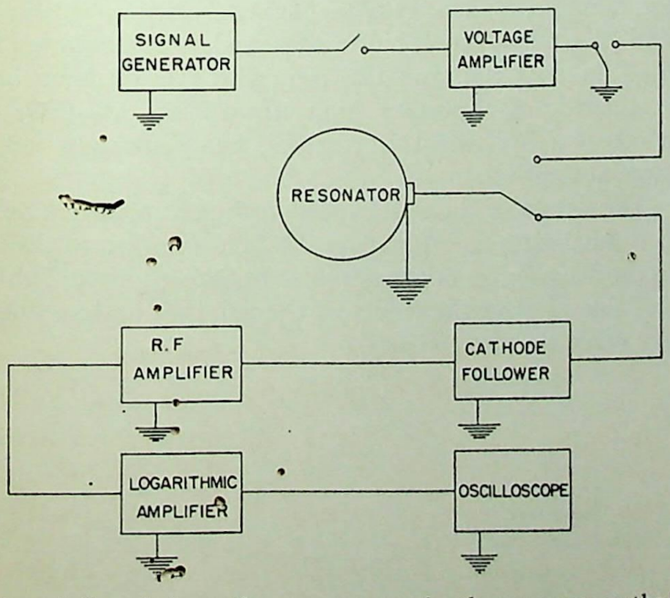

FIG. 6. Sound absorption measurement by the resonance method.

(2) *Reverberation Method*

In the reverberation method the vessel which is filled with the liquid is excited to a large number of normal modes of oscillations so that a diffuse sound field occurs. The absorption coefficient is determined from the rate of decay of the sound. The decay of sound energy is exponential provided the boundary losses affect all the normal modes of vibration nearly uniformly. The nature of the sound field does not matter so long as the sound field is almost uniform throughout the volume of the liquid. If the walls of the container are irregular or very symmetrical, standing wave patterns do not offer any serious problem. Scattering of the sound field, instead of leading to erroneous absorption, helps in achieving the diffuse sound field. The vessel used by Tamm and Kurtze is a seamless cylindrical 100-liter vessel (54 cm in diam and in height) made of pure anodized and varnished aluminum, 3.5 mm thick.

According to Mulders[58] the time constant of the decay of sound amplitude not only depends upon the absorption of ultrasonic waves in the liquids but also on other causes such as the radiation of sound energy into the air and the energy losses by the friction of sound waves along the walls. According to him the decay constant can be expressed as a function of the dimensions of the vessel. In the case of a cylindrical vessel of radius R and height H filled with a liquid of density ρ and shear viscosity coefficient η, the observed decay constant δ is given by

$$\delta=\alpha C+1.18[(2/R)+(1/H)](f\eta/\rho)^{\frac{1}{2}}+(140/\rho H), \quad (86)$$

neglecting the absorption in the attachment of the vessel and the microphone, etc. The second term represents corrections due to the friction of the walls. The third term represents the correction due to radiation into air from the liquid surface, a factor which is not very important. In the case of a cylindrical vessel filled with water, Mulders found at 25°C and 1010 kc $\delta=58.5$ sec^{-1}, $1.18[(2/R)+(1/H)](f\eta/R)^{\frac{1}{2}}=26$ sec^{-1}, $(140/\rho H)=1.5$ using the constants $R=0.14$ m, $H=0.10$ m, $\rho=1000$, $\eta=0.89\times10^{-3}$, $C=1500$ msec^{-1}. Thus αC comes out to be equal to 31.0 sec^{-1} and $(\alpha/\nu^2)\times10^{15}$ m^{-1}sec^2

$=20.5$ in agreement with measurements of other workers utilizing other methods. Thus, all that is necessary is one measurement of the reverberation time, and other corrections can be calculated from the dimensions of the vessel and the physical constants of the liquid, namely, the viscosity η and the density ρ.

The schematic arrangement of the apparatus is shown in Fig. 7. After the sound source has been stopped, the sound reverberates in the vessel. This can be observed by a crystal microphone and an amplifier. The time constant of decay of sound can be measured at the output of the amplifier. Tamm and Kurtze used the frequency band for excitation of width 20 kc. This is generated by pulsing a variable carrier frequency which is restricted to five definite values, i.e., 50, 100, 200, 500, and 1000 kc. The electric output of a piezoelectric receiver, which is a measure of the sound energy in the vessel (i.e., after amplification, frequency conversion, and filtering) is recorded by a Newman type high-speed level recorder or by a log amplifier combined with an oscilloscope.

Lamb and Sherwood[60] and Karpovich[61] used this technique in the study of relaxations due to rotational isomers in cyclohexane derivatives.

IV. RESULTS AND DISCUSSIONS

(a) Values of Absorption and Relaxation Frequencies

1–1-valent electrolytes, for example, NaCl, NaBr, and KBr, have very low absorption, i.e., the solutions of these electrolytes have almost the same absorption as that of the pure water. 2–1- and 3–1-valent electrolytes as well as 1–2-valent electrolytes behave almost in a similar way to 1–1-valent electrolytes below 10 Mc. Only above 10 Mc do they exhibit measurable absorption.

2–2-valent electrolytes, in general, possess a considerably high absorption in the whole frequency range which has been investigated. In view of the fact that sulfates of bivalent metals are soluble in water and are obtained in sufficient quantities with necessary degree of purity, mostly the sulfates have been investigated; for example, $BeSO_4$, $NiSO_4$, $MgSO_4$, $CoSO_4$, $MnSO_4$, $ZnSO_4$, $CuSO_4$, etc. Thiosulfates and chromates such MgS_2O_3, $MgCrO_4$, and $CaCrO_4$, which have been investigated, also possess high absorption. $Al_2(SO_4)_3$, which is a 3–2-valent electrolyte, has strikingly very large absorption.

The values of the absorption coefficient α in decibels per unit length as referred to 0.1-M/l solution at 20°C in the electrolytes investigated so far are given in Table I. Table II gives the values of the primary and secondary relaxation frequencies.

Figure 8(a) represents a summary of all measured frequency curves by Tamm and Kurtze at 0.1 M/l. Figure 8(b) shows α/ν^2 for 0.1-M/l solutions plotted against frequency (Tamm and Kurtze[16b]).

(b) Effect of Concentration on Absorption

In nearly all of the 2–2-valent electrolytes investigated the absorption is approximately linearly dependent upon the concentration in the concentration range from 0.001 to 0.1M/l (Tamm and Kurtze). The absorption cross section Q is defined by

$$Q = 2\alpha/nL, \tag{87}$$

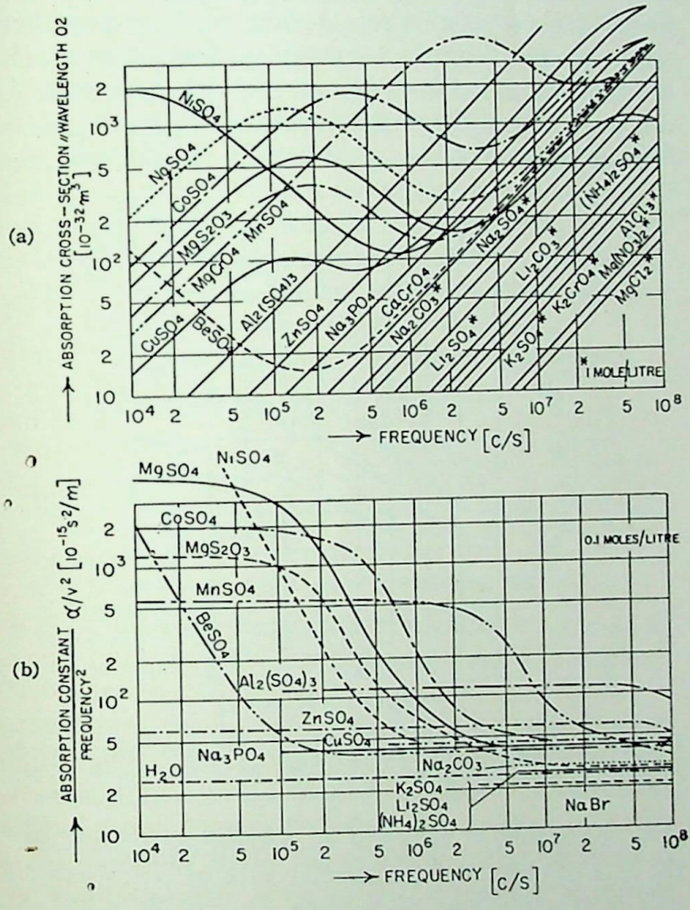

FIG. 8. (a) Sound absorption spectra of electrolytes in aqueous solutions at 20°C according to measurements of Tamm, Kurtze, and Kaiser (relative to water) for 10^{-2} to 10^{-1} M solutions. (b) α/ν^2 for 0.1-M/l solutions of some electrolytes plotted against frequency. [In Fig. 8(a) read $MgSO_4$ for $NgSO_4$ and replace "//" by "×" before and "02" by "$Q\lambda$" after wavelength.]

where n is the concentration in moles per liter and L is the number of molecules per mole. This can be written as

$$Q[m^2] = 1.66\times10^{-25}[2\alpha(\mathrm{cm}^{-1})/n(\mathrm{M/l})]. \tag{88}$$

The absorption cross section is thus found to be constant in the range 0.001 to 0.1 M/l. Figure 9 shows the dependence of the absorption cross section Q of $MgSO_4$, $MnSO_4$, $ZnSO_4$, and $CuSO_4$ on concentration (Tamm and Kurtze[16c]). Wilson carried out the measurements on the concentration behavior of the excess sound absorption in $MgSO_4$ in the concentration range from 0.003 to

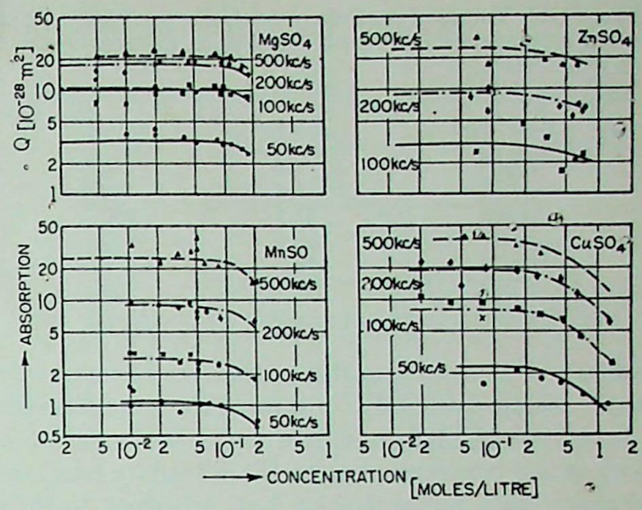

FIG. 9. Dependence of the absorption cross section (Q) of $MgSO_4$, $MnSO_4$, and $CuSO_4$ on concentration.

0.02M. According to him the relationship between the excess sound absorption and the concentration is nonlinear; in fact, the absorption cross section tends to zero as the concentration goes to zero. Table III gives the values of the maximum absorption per wavelength in $MgSO_4$ solutions at several concentrations, temperature being 23° to 25°C.

Kor and Verma[23] have studied the concentration behavior of $MnSO_4$ in great detail from 0.0025 to 1.0M. The relationship between the excess sound absorption and the concentration is found to be linear from 0.02 to 0.1M (Fig. 10), but becomes nonlinear both below 0.02M (Fig. 10) and above 0.1M (Fig. 11). The absorption cross section is constant over the range 0.02 to 0.1M and then diminishes as the concentration increases beyond 0.1M. As the concentration is lowered below 0.02M, the absorption cross section increases.

(c) Effect of Concentration on Relaxation Frequency

According to Wilson's measurements in $MgSO_4$, the relaxation frequency remains approximately constant in the range of concentration from 0.003 to 0.02M.

TABLE II. Values of primary and secondary relaxation frequencies in some of the electrolytes.

Electrolyte	Primary relaxation frequency	Secondary relaxation frequency
$FeSO_4$	10^3 cps	300 Mc
$NiSO_4$	10^4 cps	...
$MgSO_4$	130 kc	200 Mc
MgS_2O_3	180 kc	No relaxation in 100–300 Mc
$MgCrO_4$	180 kc	200 Mc
$CoSO_4$	400 kc	200 Mc
$MnSO_4$	3 Mc	30 Mc
$ZnSO_4$	200 Mc	...
$CuSO_4$	150 kc	>100 Mc
$Al_2(SO_4)_3$	20 Mc (very low conc.)	...
$La(NO_3)_2$	50 Mc	...

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

TABLE III. Values of maximum absorption per wavelength and relaxation frequency in $MgSO_4$ solutions at different concentrations at 23°–25°C.

Conc. M/l	$\mu_m \times 10^6$	ν_m (kc)
0.003	4.6	130
0.0053	15.5	140
0.008	25.5	140
0.01	35.5	130
0.014	48	138
0.02	80	150

Tamm and Kurtze also report that the relaxation frequency is approximately constant in the range from 0.01 to 0.1M. In $MnSO_4$ Smithson and Litovitz report no effect of the concentration on the secondary relaxation frequency with concentration but, according to them, there is indication of a small increase beyond 0.1M. According to Kor and Verma the relaxation frequency is independent of the concentration in the range 0.02 to 0.1M but increases with concentration in the range 0.0025 to 0.02M. It again increases with concentration above 0.1M.

Smithson and Litovitz argue that the specific reaction rate k_1 is concentration dependent too (which has been neglected in the past) and the effect of increasing the ionic strength by increasing the concentration is always to increase the reaction rate, whatever may be the nature of the reaction whether it is between two ions of same sign or opposite signs or between ions and neutral molecules. Hence very small concentration dependence of the reaction rate may favor the reaction between two dipoles. Dissociation of an ion pair also remains a possibility, but at present there is no theory for the effect of ionic strength on the dissociation of an ion pair.

(d) Effect of Dielectric Constant

According to Tamm and Kurtze the electrolytic dissociation is caused by the dipole forces of the molecules of the solute, a measure of this dissociation is the dielectric constant of the liquid. In liquids with smaller dielectric constant than water, the dissociation energy therefore is larger and the relaxation frequencies shifted to lower values. Tamm and Kurtze used water-alcohol mixtures to vary the dielectric constant of the solvent and report lowering of the relaxation frequency with the decrease in the dielectric constant of the solvent. However, the maximum absorption increases in magnitude, the reason for which, according to them, most probably lies in the increase in the percentage of the undissociated molecules.

Bies used dioxane-water mixtures as a solvent. According to his measurements there is small change in the relaxation frequency with concentration. By extrapolating it to zero concentration, he determined the forward reaction rate k_1 on the assumption that the mechanism responsible for the excess sound absorption is of the dissociation type $MgSO_4 \rightleftarrows Mg^{++} + SO_4^{--}$. He found that the reaction rate k_1 first went up and then down as the dielectric constant of the solvent was lowered. He calculated the reverse reaction rate k_2 utilizing the experimentally measured values of equilibrium constant K by conductivity bridge and the

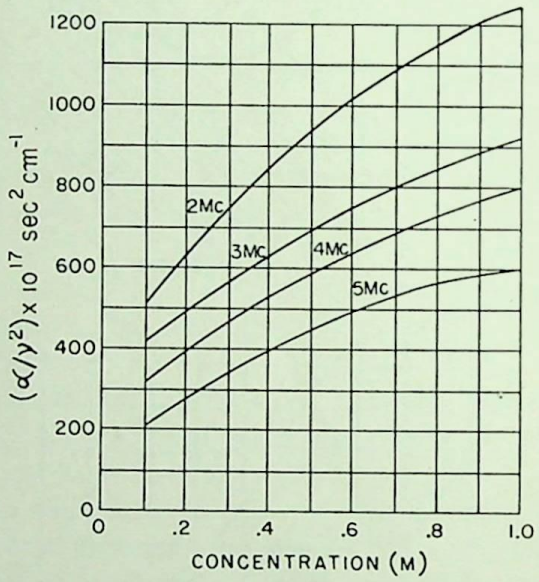

FIG. 11. Nonlinearity of the absorption coefficient with concentration at various frequencies above 0.1 M in $MnSO_4$ at 25°C.

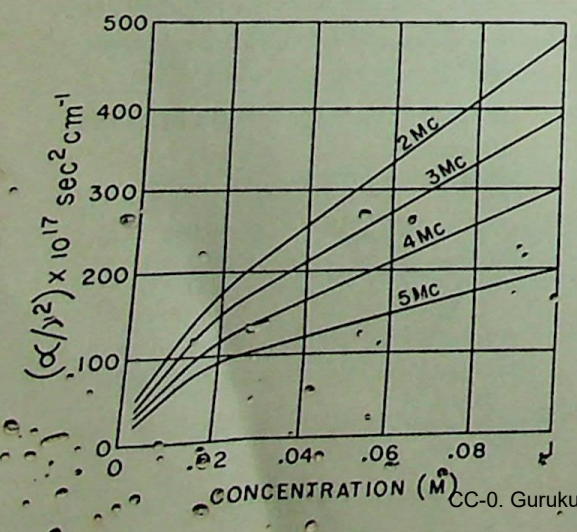

FIG. 10. Variation of the absorption coefficient (α/ν^2) with concentration (0.0025 to 0.1 M) at various frequencies in $MnSO_4$ at 25°C.

above extrapolated values of k_1. According to Laidler,[62] the rate of change of the specific rate of reaction of a pair of reacting ions of valence Z_1 and Z_2 with the reciprocal of the dielectric constant is given by the equation

$$[-d \ln k_2/d(1/D)] = (\epsilon^2 Z_1 Z_2/KTr), \qquad (89)$$

where $Z_1 = -Z_2 = 2$ in the above dissociation, r is equal to twice the mean ionic radius 3.08×10^{-8} cm, K the Boltzmann constant, and ϵ is the electrostatic unit of charge. Bies reported that the specific rate of association does increase with the reciprocal of the dielectric constant of the medium as it should if ions of opposite signs are involved, but apparently not in a linear fashion as expected from the above expression. However, Bies gave no explanation for his observation that the forward reaction rate went first up and then down

as the dielectric constant was lowered. At present there does not seem any explanation for this anomalous behavior of the reaction rate with respect to the dielectric constant. However, Kor and Verma report continuous increase in the reaction rate k_1 with the lowering of the dielectric constant in $MnSO_4$ solutions. They also used water-dioxane mixtures to vary the dielectric constant of the solvent.

Smithson and Litovitz used methanol-water mixtures for varying the dielectric constant. These mixtures have the advantage that water and methanol are similar and the absorption in such mixtures changes only slightly and almost linearly with percentage methanol (Burton),[63] but in this mixture both the molecules are polar and the interaction between the polar constituents of the mixtures may affect the absorption due to main dipole-dipole reaction if it is so. They find a decrease in the primary relaxation frequency by a small amount with decreasing dielectric constant. However, the secondary relaxation peak was observed to increase with decreasing dielectric constant. The magnitude of the absorption increased considerably as D was lowered.

The theory of the influence of the dielectric constant on the rates of reaction, which has experimental evidence in the case of slow reactions has been discussed in several books; see Amis,[64] Laidler,[62] or Glasstone, Laidler, and Eyring.[65] Table IV, presented by the latter authors, shows the effect of dielectric constant and ionic strength on the rates of a reaction. According to Smithson and Litovitz, the lowering of the primary relaxation frequency with the decrease in the dielectric constant suggests that the forward reaction is either between ions of like sign or between dipole molecules. Either of these reactions would be of the first order if one of the reactants were present in great excess and would behave like a dissociation process.

TABLE IV. Effect of dielectric constant and ionic strength on the rates of a reaction.

Reaction type	Effect of increasing dielectric constant	Effect of increasing ionic strength
1. Two dipole molecules	increase	no effect
2. Two ions		
(a) same sign	increase	increase
(b) opposite sign	decrease	increase
3. Ion and neutral molecule	decrease	increase

However, the reaction involving two charged ions of the same sign does not seem to satisfy the condition of large excess. Hence, they conclude in favor of a forward reaction between solute molecules (ion pairs) and the dipole solvent molecules, and the excess of the solvent assures that the reaction is of the first order.

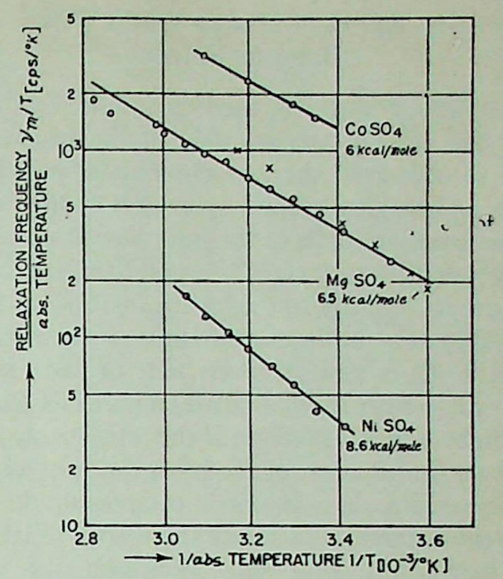

FIG. 12. Temperature dependence of the relaxation frequency: ν_m/T *vs* $1/T$ for $CoSO_4$, $MgSO_4$, and $NiSO_4$.

(e) Effect of Temperature

The relaxation frequency ν_m increases with increase in temperature, while the maximum excess absorption is not altered appreciably. A plot of $\log\nu_m/T$ *vs* $1/T$ gives a straight line, as found by Wilson for $MgSO_4$, by Tamm and Kurtze for $MgSO_4$, $CoSO_4$, and $NiSO_4$ (Fig.12), and by Smithson and Litovitz, and Kor and Verma for $MnSO_4$. The experimental activation energy for the relaxation process obtained from the slope of the above curve are about 6.5 kcal/M for $MgSO_4$, 8.6 kcal/M for $NiSO_4$, about 6 kcal/M for $CoSO_4$. In $MnSO_4$ Smithson and Litovitz found activation energy to be 8.68 kcal/M in the isodielectric solution. Isocomposition measurements were made with two different solvents, pure water and 29.52% methanol gave energies of 7.85 and 8.05 kcal/M, respectively, both of which are lower than isodielectric activation energy.

According to Amis and Jaffe[66] the activation energy ΔE for an ionic reaction consists of two parts, ΔE_1, which represents a contribution to activation energy due to electrostatic forces and ΔE_2, a contribution due to nonelectrostatic forces, $\Delta E=\Delta E_1+\Delta E_2$. According to Amis ΔE_1, in the case of a reaction between two bivalent ions, should be equal to 50% of the total activation energy. However, Smithson and Litovitz, using the methods outlined by Amis and utilizing their values of $d(k_1)/d(1/T)$ and $d(k_1)/d(1/D)$, find ΔE_1 to be just equal to 8% of the total activation energy. Such a low value of the activation energy for the electrostatic contribution, according to them, rules out ion-ion reaction as the rate determining step. However, such a low value may fit with the dipole-dipole reaction.

(f) Effect of Heavy Water When Used as Solvent

When heavy water is used as a solvent in place of water, the rate of the reaction in the solution is expected to change if the rate-determining step involves making or breaking a bond between a hydrogen and an oxygen atom, apart from the pure solvent effect, which is very small, since the dielectric constant of heavy water differs only by less than 1% and the viscosity by about 20%. The half-quantum zero-point energy in the case of D_2O is smaller than that of H_2O since the heavier deuterium atom oscillates more slowly compared to the lighter protium atom. If the total energy required to make a molecule react is almost the same whether it is a deuterium or a protium compound, the critical increment is larger and hence the reaction rate smaller for a deuterium compound. Smithson and Litovitz, however, notice no measurable shift in the lower relaxation peak. This means that the rate determining step does not involve the OH bond. It rules out such possibilities as Eqs. (69) or (70). However, a secondary relaxation peak is not observed in D_2O solvent. This might be due to the OH bond which might have shifted out of the frequency range or that the relaxation which is normally observed at about 200 Mc in H_2O solution is shifted down so as to obscure the small peak.

(g) Effect of Pressure

Fisher[67] for the first time reported that acoustic absorption in $MgSO_4$ solutions shows a considerable decrease with elevated pressure. Absorption measurements were made near 100 kc by means of a resonant cylindrical steel cavity which could be pressurized. Observations at several frequencies in this region give the pressure dependence of the relaxation frequency. Carnevale and Litovitz[68] have also studied the effect of pressure on ultrasonic relaxation in manganous sulfate and ammonium hydroxide. Absorption data were obtained for $MnSO_4$ at frequencies from 9 to 75 Mc/sec up to pressures of 3930 kg/cm^2 and a temperature of 60°C. The relaxation frequency increased from 19.1 Mc/sec at atmospheric pressure to 30.7 Mc/sec at 3930 kg/cm^2. Absorption measurements in NH_4OH were obtained at frequencies from 15 to 75 Mc/sec up to pressures of 2030 kg/cm^2 and a temperature of 45°C. The relaxation frequency increased from 21.2 Mc/sec at atmospheric pressure to 52.0 Mc/sec at 2030 kg/cm^2. The results are explained on the basis of chemical dissociation.

ACKNOWLEDGMENTS

The author wishes to acknowledge with thanks the helpful discussions he has had with Professor Ernest Yeager. He is especially grateful to Professor K. Bannerji for his valuable suggestions. Special thanks are also due Professor Frank Hovorka for the grant which made possible his stay at Western Reserve University and for the facilities which enabled him to complete this article. Finally, the author also wishes to thank Mr. Jacob Schrope for his help in the preparation of the diagrams.

Anisotropic Light Scattering of Streaming Suspensions and Solutions

WILFRIED HELLER

Chemistry Department, Wayne State University, Detroit 1, Michigan

I. INTRODUCTION

IN recent years considerable use has been made of light scattering for determining the shape of dissolved macromolecules and of dispersed colloidal particles. The favored method uses the variation of scattering with the angle of observation. The theories used are due to Gans[1] and Debye.[2] An alternative method is that of Krishnan.[3] Here, the relative intensities of the "four Krishnan components" of light scattered at 90° with respect to the primary beam are the experimental data. The former method uses incident natural light; the latter, incident plane polarized light. Both have in common the investigation of light scattering by systems with randomly oriented molecules or particles. There is no need for a review of either of these methods since several excellent summaries are already available.[4] A much neglected, yet more powerful and older third method, is due to Diesselhorst and Freundlich.[5] In this, the light scattering is observed subsequent to an orientation of the scattering bodies, e.g., by streaming. Such an orientation produces an anisotropy of light scattering: the scattered intensity varies with the orientation of the electric vector of the incident beam with respect to the morphologically extraordinary direction of the scattering bodies. This review is concerned with the three principal phenomena of anisotropic light scattering observed or to be expected: dityndallism, conservative dichroism, and "bidissymmetry."

II. METHODS AND PROBLEMS OF ORIENTATION

The necessary orientation of particles or molecules may be produced by streaming, or by an electric or magnetic field. Flow orientation is due exclusively to anisometric (nonspherical) shape and is therefore of primary interest here. It is "kinematic"—although the particles rotate continuously due to the velocity gradient q and to the rotatory Brownian movement, they spend most of their time in a position defined by the angle χ. This is the angle between the most probable direction of the longest dimension of the particles and the direction of the velocity gradient. If the particles or molecules are deformable, the phenomenon is complicated by dilation at an angle of 45° with respect to q and the direction of flow, and compression at an orthogonal angle. The direction of flow is generally referred to as the extraordinary direction e of the system. It will actually be an extraordinary direction only if $q \rightarrow \infty$, i.e., when the longest dimension of the particles is parallel to the direction of flow ($\chi = 90°$). If the particles are uniaxial, the direction of flow becomes then—according to the definition in crystal optics—the optic axis of the system and, therefore, the optically extraordinary direction.

Magnetic and electric orientation are simpler in nature since the direction of orientation always coincides with the direction of the field or with the direction normal to it. The degree of orientation is governed here by the torque acting upon the particles and the superimposed randomizing effect of the rotatory Brownian movement. Complications arise from the fact that magnetic and electric orientation may be due to both anisometry and intrinsic (magnetic or electric) anisotropy. Since the orienting torque due to anisometry is generally very weak the orientation is, in general, mainly due to a permanent or induced magnetic or electric dipole. The existence of the two torques can lead to considerable complication if they are orthogonal. The orientation may then change direction with field strength, temperature, or frequency. Some of the resulting optical complications are described in detail elsewhere.[6] Of particular interest is the application of alternating magnetic[7] or electric[8] fields. Whenever magnetic orientation is applicable, it deserves preference over electric orientation because of a variety of possible secondary complications of the latter.[8]

III. DITYNDALLISM

1. Classical Experiments and Definitions

Dityndallism was discovered by Diesselhorst and Freundlich[5] on various streaming colloidal solutions.

Y	X	Z	○	○

FIG. 1. Dityndallism produced by flow orientation of colloidal rods and plates. ●, scattered intensity is strong. ○, scattered intensity is weak.

Figure 1 illustrates their procedure and results. The colloidal solution flows through a rectangular cell in the x direction. The principal velocity gradient is in the z direction and a secondary gradient is in the y direction. Consequently, rod-like particles will, at a sufficiently high velocity gradient, direct their morphologically extraordinary direction, i.e., the major axis, preferentially toward x, while disk-like particles will direct theirs, the shortest dimension, preferentially toward z. The direction of the linearly polarized beam and of its electric vector and the direction of observation (always perpendicular to the incident beam) are varied to the fullest possible extent.

The black and white disks indicate that the observed scattered intensity is weak or strong, respectively.[9] It follows that, for one particle, the intensity of light scattered at 90° with respect to the incident beam is strongest if the electric vector is perpendicular to the plane of observation and parallel to the largest dimension of the particle. The laterally observed Tyndall beam of a dispersed system of oriented rods has therefore maximal intensity if the electric vector of the incident beam vibrates, for $q \to \infty$, parallel to the direction of flow and has minimal intensity for the orthogonal direction of vibration. This effect, called "dityndallism," [10a] could be defined in analogy to birefringence and dichroism by

$$(D_o)_\theta = (I_e - I_o), \qquad (1)$$

where I is the intensity of light scattered at an angle θ, per unit solid angle, per unit volume of unit concentration, and per unit intensity of the incident beam, and o refers to the ordinary direction of the system. The usefulness of this definition is limited, however, since $(I_e - I_o)$ may be finite also in the unoriented system. An alternate definition,

$$(D)_\theta = (I_e' - I_e'') - (I_o' - I_o'') = \Delta I_e - \Delta I_o, \qquad (1a)$$

therefore may be introduced as preferable. The superscripts $'$ and $''$ refer to the oriented and unoriented system, respectively. For practical work, definition (1a) may be expressed in terms of more convenient intensity ratios.[10b]

Flow dityndallism is an exclusive form effect only if produced by deformation of isotropic fluid material

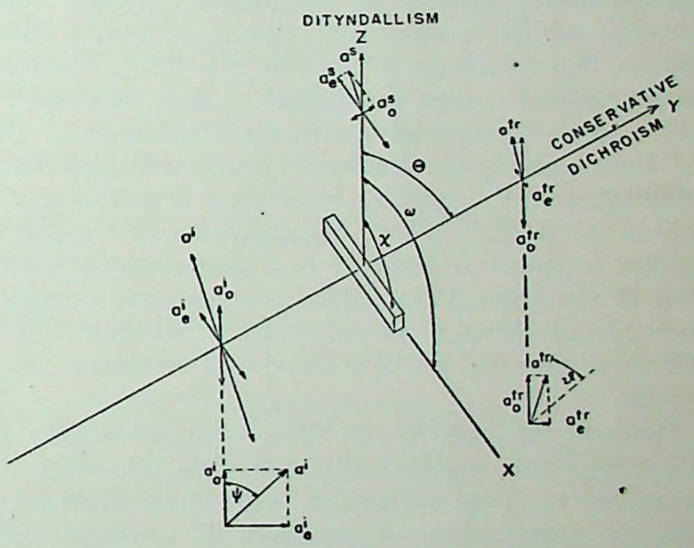

FIG. 2. Geometrical definitions pertinent to flow dityndallism and conservative flow dichroism.

(e.g., emulsion droplets) or by orientation of anisometric intrinsically isotropic bodies. Anisometric bodies are rarely intrinsically isotropic. In general, therefore, an intrinsic dityndallism of equal or opposite sign will be superimposed upon the form dityndallism. A quantitative differentiation between the two effects should be possible by varying the refractive index of the medium.

2. Physical Optics of Dityndallism

The physical optics of dityndallism *is* somewhat intricate. This is discussed with *the aid* of Fig. 2, where the principal drawing is *in perspective*, while two auxiliary drawings pertain *to the xz* plane viewed in the direction of the light *source*. The symbols x, y, and z indicate the direction *of flow* of the primary beam and

[9] A quantitative investigation can be expected to show that there are four different intensities for platelets and three for rodlets.

[10a] H. Zocher, Kolloid Z. 37, 336 (1925).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

of the velocity gradient, respectively. The angle χ between the major axis of the rod-like particle considered and the velocity gradient is, for simplicity, assumed to be 90°. This corresponds to $q \rightarrow \infty$. The angle between the electric vector of the incident beam and the yz plane is ψ, that between the vector of the scattered beam—or of the scattered component considered—and the xz plane is ψ' (symbol not shown in Fig. 2). The angle between the variable plane of observation and the direction of flow is ω, that between the direction of observation and the direction of the primary beam is θ.

Consider first the situation pictured in Fig. 2, in which $\theta=\omega=\chi=90°$ and let the angle ψ be 90° and 0° in two *consecutive* measurements. The amplitude of the component of the incident beam vibrating in the extraordinary direction a_e^i gives rise to an amplitude of the scattered component a_e^s, and, in the more general case, of a component $a_o^{s'}$. The latter is not considered in the drawing. Similarly, a_o^s (and a neglected component $a_e^{s'}$) will result from a_o^i.[11] Since $a_e^s \neq a_o^s$, the consecutively determined amplitudes of the components of the transmitted beam, $a_e^{tr} \neq a_o^{tr}$. Next assume that $\theta=\omega=\chi=90°$, but $(0° \neq \psi \neq 90°)$. The scattering process is then equivalent to that expected for two coherent components with the amplitudes a_e^i and a_o^i. Consequently, the scattered linearly polarized beam, of amplitude a^s, resulting from their interference, vibrates at an angle $\psi' \neq \psi$. Measurement of the dityndallism is therefore reduced to a single measurement, that of the angle ψ' for which the scattered intensity transmitted through an analyzer is maximal.[12] The difference between ψ and ψ' reaches a maximum when $\psi=45°$.

When $\theta=90°$, $\omega \neq 90°$, $\chi=90°$ (and $0° \neq \psi \neq 90°$), the scattered beam is elliptically polarized, the ellipticity being due to phase differences between the orthogonal coherent components of wavelets of scattered light originating in different volume elements of the particle. The situation is the same when $\theta=\omega=90°$, $\psi=0°$, but $\chi \neq 90°$.

This discussion allows one to anticipate a few physical phenomena which have yet to be verified experimentally. It should be possible to determine χ by rotating the direction of observation, in the xz plane, to the particular $\omega \neq 90°$ value at which the ellipticity vanishes, i.e., at which the scattered beam represents linearly polarized light. The rate of change of the state of polarization during this rotation should vary with the shape of the particles. This should provide an auxiliary method for the determination of shapes. Assume that the proper ω value yielding linearly polarized light is found: a transition from $\theta=90°$ to $\theta \neq 90°$ will then also produce ellipticity and the rate of its change with θ also should vary with the dimensions of the particles or molecules.

The case may arise that ellipticity is observed even for $\theta=\omega=90°$, $\chi=90°$, and $0° \neq \psi \neq 90°$. This would be indicative of intrinsic anisotropy and the degree of ellipticity would be indicative of the magnitude of intrinsic anisotropy. Ellipticity would be due here to the difference in retardation of the orthogonal components of scattered light within the scattered particle by virtue of differences in its refractive indices parallel and perpendicular to the rod axis. This effect would represent the true complement, in the scattering process, to intrinsic birefringence.

3. Theory of Dityndallism

The theory of dityndallism is concerned with the scattering process of nonspherical particles and with the distribution function of their principal axes. The latter was treated first by Langevin[13] for the relatively simple case of magnetic (or electric) orientation. This theory yields the relationship

$$(\mu_e-\mu_u)(\mu_u-\mu_o)=2.0, \qquad (2)$$

where the subscript u refers to the unoriented system and μ is the refractive index. The relationship should, of course, hold also for turbidity and true absorption. It was verified for the former effect.[14] The distribution function for electric orientation of flexible macromolecules was derived, more recently, by Isihara.[15] The more complicated case of flow orientation of rigid spheroids has been treated by Boeder[16] and, more rigorously, by Peterlin and Stuart.[17] Finally, the distribution function for the end-to-end distance of flow deformed molecules has been developed recently.[18]

The theory of anisotropic scattering for the case in which intrinsically isotropic and rigid anisometric particles are small compared to the wavelength of the incident beam is implicitly contained in an early treatment by Rayleigh.[19] A recent extension of this theory by A. F. Stevenson includes the dimensions commonly encountered with proteins and synthetic macromolecules. This theory will be published in the near future.

---

[11] Owing to the interference of each of the two disregarded components *with* the respective coherent orthogonal components, a linearly polarized beam results in each instance which vibrates in reality at an *angle* $\psi' \neq 0°$ and $\psi' \neq 90°$, respectively. It is surprising that in depolarization measurements on resting solutions by Krishnan's method *no attention* has been paid either to the existence of these two linearly polarized scattered beams or to their measurement.

[12] Similarly V_v+V_h and H_v+H_h could be determined in one measurement and the four "Krishnan-components" V_v, V_h, H_v, and H_h in two measurements instead of the four generally used in depolarization measurements on unoriented systems.

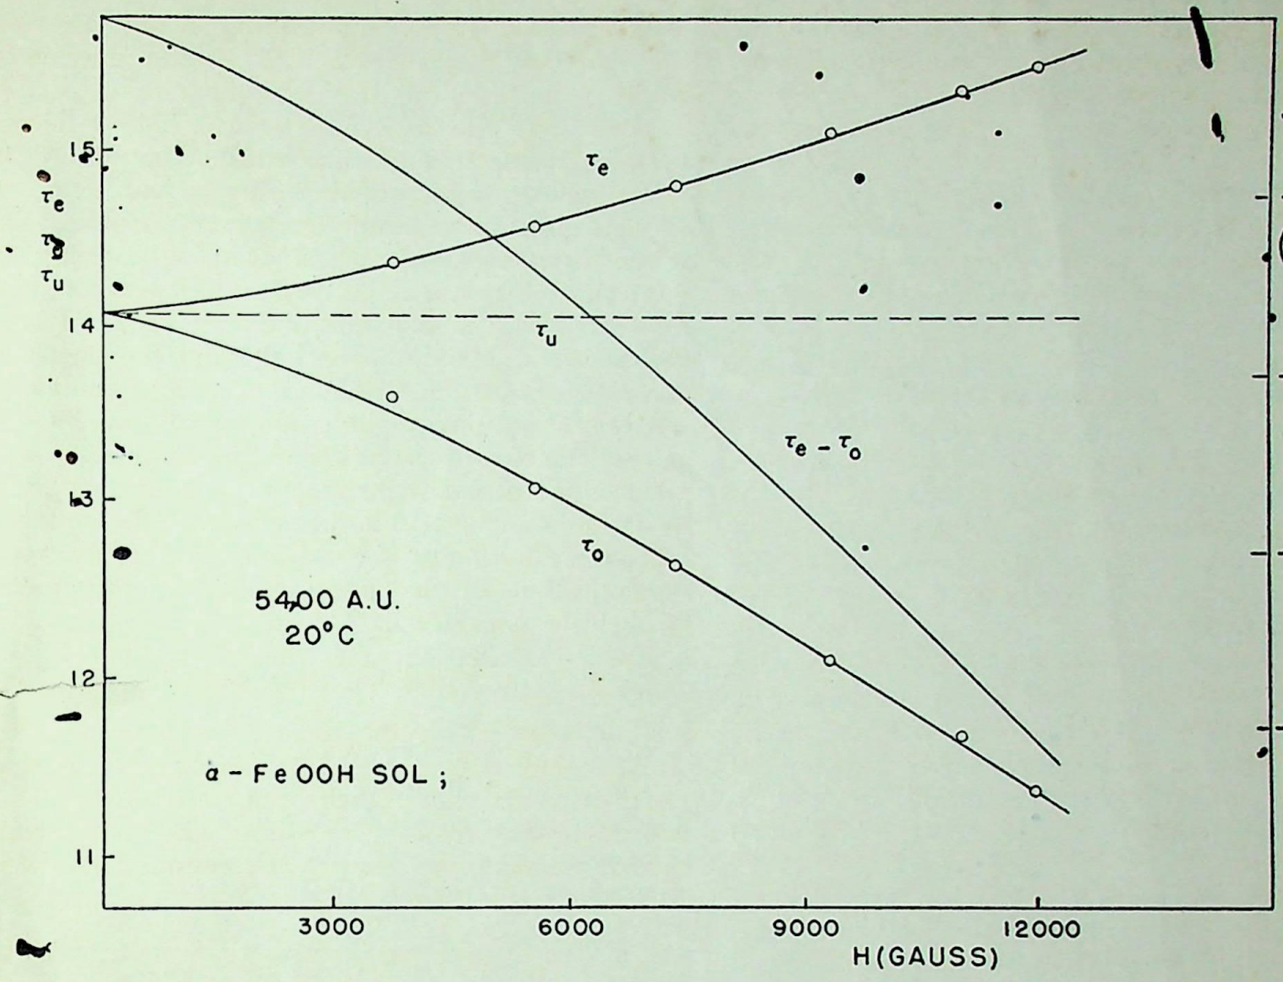

FIG. 3. Conservative magnetic dichroism of an α-FeOOH-sol.

The treatment of anisotropic light scattering to be expected from random coils deformed by flow is difficult, and suitable approximations are therefore necessary. Exploratory investigations to that effect have been published elsewhere.[20,10b]

IV. THE CONSERVATIVE DICHROISM

1. Definitions and Methods of Measurement

Figure 2 shows that the turbidity τ of a dispersed system of oriented anisometric particles varies with the direction of the electric vector of the incident linearly polarized beam. Consequently, the difference $(\tau_e - \tau_o) \neq 0$.[21] The existence of this effect was explicitly proved only rather recently.[6] It was subsequently designated as "conservative" dichroism.[22] This effect, like dityndallism, is primarily an effect of anisometry, but again the intrinsic anisotropy may make a contribution of equal or opposite sign. If the form effect predominates, then the sign of the total effect immediately indicates the orientation of the longest particle dimension with respect to the extraordinary direction. In order to evaluate the relative contribution of the intrinsic effect, one can—as with birefringence—eliminate the form effect by suitably varying the refractive index of the medium.[23]

Investigation of the conservative dichroism requires that one work in a spectral range of negligible absorption. Otherwise, the effect observed is complex in nature because of the simultaneous presence of true dichroism which is due to a difference in the extinction coefficients ϵ_e and ϵ_o. The two effects are physically not separable.

The theory of conservative dichroism, like that of dityndallism, is implicitly contained in the paper by Rayleigh[19] when the particles are small compared to the wavelength. The theory for larger particles is, at present, under preparation. The latter case is of far greater importance since the smallness of the turbidity in systems with very small particles makes it difficult

[21] "Turbidity rations" may often be easier to obtain or may convey supplemental information. Thus, the ratios τ_e/τ_u or τ_o/τ_u, where u refers to the unoriented system, give the turbidity of the oriented system, for the particular direction of the electric vector, relative to that of the isotropic unoriented system.

to obtain a reliable turbidity difference $(\tau_e - \tau_o)$. Although the attractive feature of conservative dichroism, like that of dityndallism, is primarily the possibility of obtaining numerical data on the dimensions of nonspherical bodies, other applications also are interesting: one can easily obtain semiquantitative information on changes in size, shape, and structure of aggregates formed during coagulation of anisometric particles.[24] Furthermore, the mechanism and kinetics of sol-gel transformation and the change in rotatory mobility of particles during this process can be studied successfully.[25]

Several methods are available for experimental determination of $(\tau_e - \tau_0)$. First, by conventional spectrophotometric procedure τ_e and τ_0 may be measured in succession. The plane of polarization is rotated, between measurements, by 90° and the oriented system and the reference medium (solvent) are brought into the light path consecutively. In the case of magnetic orientation, one may use a split beam of orthogonally polarized components, each of which traverses one compartment of a twin cell filled with the oriented system and solvent, respectively. The second measurement is made after rotating the twin cell by 180° about an axis perpendicular to the field and incident twin beam.[26] Figure 3 shows the magnetic conservative dichroism thus obtained in an old colloidal solution of FeOOH.[27] (The results, to which the true dichroism makes a negligible contribution at 5400 a.u. show immediately that the plate-like particles of submicroscopic size orient themselves parallel to the lines of force.) These two methods give τ_u, in addition to τ_e and τ_o. This is not the case for the third method, which is the *fastest*, and also the most sensitive if the effects are small. *Here*, $\psi = 45°$ (Fig. 2). The conservative dichroism then produces a rotation of the plane of polarization ϑ[28] from which $(\tau_e - \tau_o)$ is easily derived.[29]

V. BIDISSYMMETRY IN UNPOLARIZED LIGHT

The rods and disks, shown schematically in Fig. 4 in the three possible orientations with respect to an incident unpolarized beam, lead to radiation diagrams of which two vectors are shown schematically in each case: the radius vector at 90° and that at 0° with respect to the direction of the primary beam. The former vector applies to observation in the plane of the paper. The reduction, by interference, in the intensity of laterally scattered light is more pronounced if the longest direction of the particle is perpendicular to the primary beam and is directed towards the observer. Again, a differentiation between rods and disks should be possible, although the quantitative differences in the optical effects can be expected to be smaller than for incident polarized light.[30] Intrinsic anisotropy also makes a contribution here, since interference varies with the refractive index.

Of particular interest is the fact that here light scattering exhibits a twofold dissymmetry. This is shown schematically in Fig. 5. The cross sections of the schematic radiation diagrams of spheres, random coils, or randomly oriented nonspherical bodies (left) and of oriented nonspherical bodies or deformed random coils

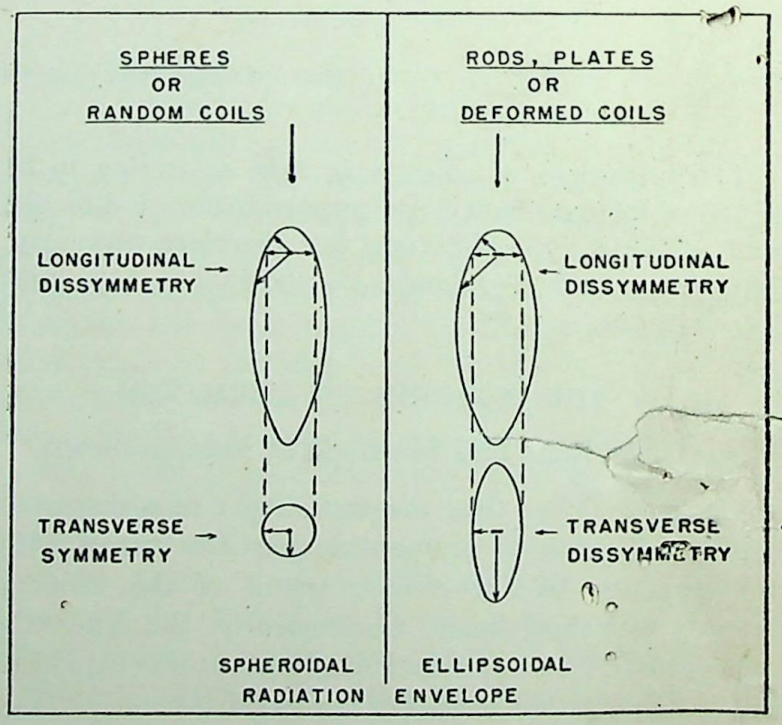

FIG. 5. Conventional dissymmetry (left) and bidissymmetry on orientation or deformation (right).

[26] The apparatus constructed and used for this purpose has been described briefly elsewhere[14] and will be discussed in detail in a separate publication.
[27] Details are given in the M. S. *thesis of G. Quimfe*, Faculté des Sciences, University of Paris (1938).
[28] The superficial similarity with rotation due to rotatory power has led a few authors to confuse dichroism with optical rotation. Rotation of the polarizer allows a very easy differentiation between the two effects.

[30] If interference in the forward direction cannot be neglected—nearly microscopic particle size or large refractive index difference between particles and medium—all three configurations of both rods and disks will lead to different scattering intensities.

(right), not negligibly small compared to the wavelength, are given by the upper drawings for the direction of the primary beam indicated by the top arrows. The cross sections of the diagrams in the lower pair of drawings apply to incidence of the primary beam perpendicular to the plane of the paper. The radiation diagram on the left exhibits merely the well-known "longitudinal" dissymmetry, while that on the right has, in addition, a "transverse" dissymmetry. Light scattering is here therefore "bidissymmetrical". The dityndallism in polarized light also exhibits bidissymmetry, but its features are more complicated.

While significant details of the scattering process are lost when unpolarized light is used, the resulting greater simplicity of the phenomena allows simplification of both the optical theory and the apparatus. One may, therefore, consider approximating treatments which would fail for polarized light. Thus, Debye's "interference" treatment[2] was used in order to establish the theory of bidissymmetry expected for flow-deformed random coils.[18] This theory allows one to derive, from the bidissymmetry, important information on molecular parameters which cannot be obtained easily by any other means.
